Predicting Bird Oiling Events at Oil Sands Tailings Ponds and Assessing the Importance of Alternate Waterbodies for Waterfowl: a Preliminary Assessment

ROBERT A. RONCONI

Department of Biological Sciences, University of Alberta, Edmonton, Alberta T6G 2E9 Canada
Present address: Department of Biology, University of Victoria, P.O. Box 3020 Station CSC, Victoria, British Columbia V8W 3N5 Canada; e-mail: rronconi@uvic.ca

Ronconi, Robert A. 2006. Predicting bird oiling events at oil sands tailings ponds and assessing the importance of alternate waterbodies for waterfowl: a preliminary assessment. Canadian Field-Naturalist 120(1): 1-9.

Tailings ponds are an integral part of oil sands mining development in northeastern Alberta, but waterfowl and shorebirds often land in these ponds during spring migration where they may become covered with oil. For decades, managers have developed and implemented methods for deterring birds from landing in these ponds, yet no deterrent strategy is fully effective. Therefore, to enhance deterrence strategies, it will be important to understand the environmental conditions that influence bird use of tailings ponds. This study quantified waterfowl flights over, and use of, tailings ponds and compared this use to waterfowl activity at natural waterbodies in the region over a single spring migration period. Results suggest that waterfowl are most likely to land on tailings ponds before lakes have thawed, after which migratory ducks appeared mainly to use natural waterbodies for migratory stopover sites. Very high numbers of waterfowl were observed on one waterbody, Kearl Lake, suggesting that this lake may be of greater importance to spring staging waterfowl than previously thought. A small sample of birds oiled at tailings ponds were examined in relation to spring weather conditions. Logistic regression analysis demonstrated that the probability of birds being oiled tended to increase with precipitation levels. Results of this study suggest that (1) preservation of natural waterbodies may play an important role in minimizing bird use of tailings ponds, and (2) future bird deterrence efforts should especially aim to deter birds during rainy weather conditions when birds may be more likely to become oiled. These results were from a small sample size, are preliminary in nature, and should be interpreted with caution. A concerted and careful effort to collect and thoroughly analyze long-term records of oiled birds may reveal important environmental effects predicting bird oiling events.

Key Words: waterfowl, oil sands, mining, tailings ponds, lakes, weather, migration, radar, conservation, Alberta.

In northeastern Alberta, oil sands development has grown considerably over the past several decades. This industry promises to grow into the 21st century since recent oil reserve estimates have placed Canada second on the world list of oil reserves with 175 billion barrels of oil in oil sands deposits (CAPP 2003*). Although most of these reserves are extractable with new drilling technologies, an estimated 20% are recoverable only with open pit mining practices (CAPP 2003*). One of the primary environmental concerns stemming from oil sands mining is the existence of tailings ponds which have oil floating on the surface. Birds landing on these ponds might become covered in oil and die. This problem has been recognized since the initial development of oil sands mining (SCL 1973; Schick and Ambrock 1974*; Ward et al. 1976*; Hennan and Munson 1979) and significant effort has been dedicated to researching the conditions that promote and prevent birds from becoming oiled (Boag and Lewin 1980; Gulley 1980; Yonge et al. 1981*; Ronconi and St. Clair 2006; also see review by Golder Associates 2000*). Nevertheless, birds still continue to be oiled and oil sands companies carry on their search for better means of reducing these incidents.

Previous oil sands research recommended the creation of uncontaminated waterbodies in close proximity to tailings ponds, allowing birds alternate landing sites (Gulley 1980; Golder Associates 2000*). Moreover, research in other industrial contexts indicates that birds can be deterred from an area more effectively when alternate roosting sites (including ponds) are available (Martin and Martin 1984; Gosler et al. 1995; Stevens et al. 2000). Yet others have argued that such diversionary ponds would only draw more birds to the region (Allen 1990). Instead, the preservation of naturally occurring waterbodies may be an optimal solution to provide alternate landing sites for birds, particularly if these alternative bodies are already used by migrating birds in the region. Comprehensive surveys of waterfowl at the major waterbodies in the vicinity of Alber-

ta's oil sands were conducted prior to oil sands development (Hennan and Munson 1979), but the current status of these waterbodies and their use by migratory birds are unknown. Moreover, subsequent surveys of waterbird numbers at natural waterbodies (Shortt 1985*; Van Meer and Arner 1985*) did not compare levels of bird activity between these natural ponds and nearby tailings ponds. Such information would make it possible to assess the importance of alternative waterbodies as stopover sites during migration, and to assess temporal changes within seasons in the attractiveness of tailings ponds to waterfowl.

In addition to information about the alternative stopover sites for migrating birds, researchers and managers have also sought to understand the conditions under which birds become oiled on tailings ponds. Over a three-year period, Gulley (1980) identified three main conditions as determinants of the numbers of birds that were killed each year. First, more birds were oiled when more birds were migrating (Gulley 1980), though the synchrony of migration is not fully predictable and tends to vary among both years and species (Bellrose 1976). Second, cold spring weather and delayed ice break-up correlated with bird oilings. Finally, greater than average seasonal rainfall has been correlated with higher rates of oiled birds. In contrast, other studies failed to observe any environmental (wind, temperature, precipitation) effects on the probability of bird landings in tailings ponds (Ronconi and St. Clair 2006). Yet neither analysis examined the frequency of bird oiling events in relation to daily weather patterns and this information may be most likely to reveal the causes of variation.

The study is situated at one of more than 10 oil sands tailings ponds operating in northeastern Alberta (Golder Associates 2000*), all of which are situated along a major migratory flyway for waterfowl traveling to the Peace-Athabasca Delta, an internationally significant staging area (Bellrose 1976; Hennan and Munson 1979). The objectives in this study were three-fold. First, I examined the seasonal abundance and direction of migratory bird movements over tailings ponds. Second, I compared numbers of waterfowl that landed at tailings ponds with numbers of birds at natural ponds in a broader region and with historical data. Finally, I assessed potential correlations between daily weather conditions and the frequency of oiled birds found during April and May of 2003. Because data were available only for a single season, I present these as preliminary results and encourage future researchers to investigate these findings over longer time periods.

Methods

The study was undertaken at the Muskeg River Mine (MRM), Albian Sands Energy Ltd., located approximately 75 km north of Fort McMurray, Alberta (Figure 1). During April and May 2003, the mine was beginning initial oil production stages. The tailings pond complex consists of three ponds totaling ~ 740 ha of surface area when full, but water coverage during this study period was approximately 530 ha. Natural waterbodies were selected for surveys based on accessibility, size, and proximity to the MRM tailings ponds. These included two lakes near the mine, four lakes south of the mine near other oil sands development, and eight lakes north of the mine that were isolated from development (Figure 1). As these lakes were situated along a North-South axis relative to the MRM, all lakes were potentially usable by waterfowl migrating along this corridor.

Airport radar systems have been used to study bird migration patterns in Alberta (Richardson and Gunn 1971), and marine radar has been used by ornithologists to study various aspects of bird activity (Cooper et al. 1991; Burger 1997; Bertram et al. 1999; Gauthreaux and Belser 2003). In this study, marine type radar was used to assess spring migratory activity over the MRM tailings ponds between 3 and 29 May 2003. Migratory activity was measured by the groups of birds flying over the study area (groups rather than individuals are identifiable by radar) and the direction of flight. Radar observations were made from 0.5 hours before sunrise to 4 hours after sunrise. This period was considered a high migratory period in northeastern Alberta (Richardson and Gunn 1971). Owing to some technical difficulties, directional data were not recorded for the first four days of this period, and data collection was not possible on six other days because of heavy precipitation that obscured radar observations.

Tailings pond and lake surveys were conducted from fixed observation points using binoculars and spotting scopes. Tailings ponds were surveyed regularly from 18 April to 29 May, and lakes were surveyed 9 to 28 May as most lakes were still completely or partially frozen during the first week of May. Observers counted individual ducks, gulls, coots, loons, and grebes on the water. No more than two or three geese were observed during any lake count; therefore, goose counts were omitted from the results. Because of the large size of McCleland Lake, all portions of it were not simultaneously visible, thus counts were only a minimum estimate of bird numbers on that lake. Kearl Lake was surveyed more often than the other natural waterbodies because it was nearest to the MRM tailings ponds and thus most likely to offer an alternate landing site for migratory birds. During the mid-1970s Mildred Lake was dammed, converting most of the lake into a tailings pond and leaving only a portion of the lake in its semi-natural state. Surveys of Mildred Lake included only the semi-natural portion. When applicable, results were compared to previous surveys (see Hennan and Munson 1979 for detailed waterfowl surveys in the region).

Reports of oiled birds on the tailings ponds were collected from 10 April to 29 May, inclusive. Although systematic searches for oiled birds were not conduct-

ed, observers spent 4 to 8 hours observing waterfowl at the tailings ponds on most days thus ensuring some consistency in effort throughout this period. Weather data for wind speed and direction, temperature, and rainfall were recorded from meteorological stations on site, and snowfall events were converted into rainfall equivalency. Mean temperature is reported here as the daily mean of maximum and minimum temperatures. Wave conditions on the ponds and percent cloud cover were recorded by observers. All occurrences of oiled birds are reported (below); however, analyses of weather effects were conducted only on oiled birds that were still alive when found, an assumption that those birds became oiled either the day they were found or the previous night. For analysis by logistic regression, oiled birds were the dependent variable (1 = days with oiled birds; 0 = days with no oiled birds). Days when observers were not present on site were excluded from analyses. Weather data were the independent variables (wind, temperature, precipitation, wave conditions, % cloud cover). Except for wave conditions, analyses of weather effects were assessed for three time periods: date of oiled bird finding, one day prior (i.e. previous 24 hour conditions), and two days prior (i.e. previous 24-48 hour conditions). Wave condition was only analyzed for the first two time periods since it was considered likely that rough water effects would not persist for as long as two days. Logistic regression analysis (SPSS 11.5) was used to assess weather effects and to build a model for predicting their effects on the probability of birds being oiled. Owing to small sample sizes of data from a single season, a liberal alpha value (0.10) was used for logistic regression analysis. Tests were conducted for inter-

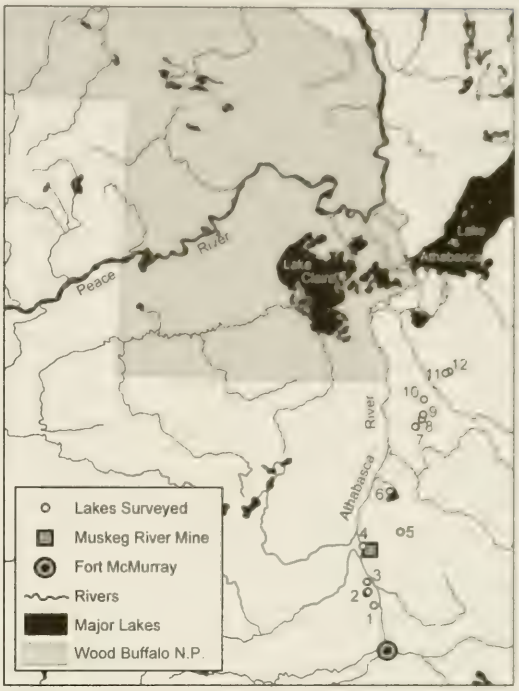

FIGURE 1. Map of study area showing the location of the Muskeg River Mine and surrounding natural waterbodies surveyed in 2003. actions and confounding variables. For detailed description of the model-building approach see Ronconi and St. Clair (2006) and Hosmer and Lemeshow (1989).

Results

Counts of bird groups by radar provided an indication of overall bird activity relative to the numbers of birds landing at tailings ponds. The radar system was operational from 3 – 29 May, during which two peaks in migratory activity were observed (Figure 2). Peaks in migratory flights (NW & N flights) coincided with two peaks in bird activity (bird groups per hour). However, a third peak in groups per hour on 27 May showed no corresponding peak in NW & N flights. Notwithstanding the three peaks, these data document high migratory volumes over most of May when counts of waterfowl on lakes were conducted. However, the numbers of ducks that also landed on the tailings ponds (Table 1) were consistently low over this same period with no comparable peaks.

Counts of birds at tailings ponds and natural waterbodies showed much variability and peaks occurred at different times for different lakes. Counts of ducks and other waterbirds at the MRM tailings ponds (Table 1) showed peaks in activity from 26 April through to 6 May, after which activity dropped considerably and remained low throughout May. Conversely, high counts of birds on surrounding lakes were observed in May (Table 1), though comparable counts from April were not possible because the natural waterbodies were still frozen at that time. In particular, Kearl Lake showed a peak around mid May with an estimated 2700 ducks

and 300 gulls on 15 May. As numbers were low at Kearl Lake in early May, these data, in combination with low May counts at tailings ponds, suggest that bird use of tailings ponds may have shifted to natural waterbodies for much of May. North of MRM, counts showed very low numbers except for McCleland Lake with over 600 ducks on 23 May. This high count suggests that McCleland was still being used as a migratory stopover at this time, but lakes farther north were likely only occupied by small numbers of breeding pairs. Between 25 and 27 May, counts of lakes south of MRM had higher numbers than maximum counts at MRM tailings ponds throughout April or May, but by this date many of these birds may have been resident breeders.

Although duck use of tailings ponds appeared low in comparison with natural waterbodies, overall duck numbers for this region were higher than historical surveys reported. Comparisons with Hennan and Munson's (1979) surveys showed several changes (Table 2). Duck numbers at McCleland Lake fell within the range of historical counts and were higher than four of the five years surveyed between 1973-1977, even though McCleland was only censused once in 2003. The highest count at Kearl Lake in 2003 was 4.6 times the maximum recorded by once annual surveys between 1973 and 1977. South of the MRM, Mildred Lake showed no use in 2003, in contrast to abundant use in previous surveys, whereas numbers were higher at Ruth Lake than were recorded during the 1970s. Due to inconsistencies in data collection methods and dates of surveys, we can not speculate on trends or changes in waterfowl abundance since the 1970s. However the dramatically high count of ducks on Kearl Lake suggest that this lake may be more heavily used as a migratory stopover site than might have been suspected from earlier surveys.

Fifteen oiled birds were observed at the MRM tailings ponds during the study period (Table 3), nine of which were alive when found. Of these, four Lesser Scaup (*Aythya affinis*) were lightly oiled and able to fly, making it probable that these were non-fatal oiling events. The remaining live oiled birds included one goose, one shorebird, one gull and two ducks. Days when live oiled birds were found were plotted in relation to weather variables (Figure 3). A logistic regression analysis was conducted on 47 days of observations, six of which had reported live oiled birds. This analysis found no effect of temperature, sea-state, wind direction, or cloud cover. Univariate analyses found date ($P = 0.160$) to be marginally significant, and rainfall ($P = 0.086$), rainfall during the previous 24 hours ($P = 0.066$), and wind speed during the previous two days ($P = 0.050$) as significant variables affecting the probability of birds being oiled. However, when combined in a multivariate analysis no variables retained significance but the two rainfall variables were only

TABLE 2. Comparisons of spring 2003 duck counts with historical counts from 1973-1977 (Hennan and Munson 1979).

[1] For 2003 surveys the entire lake was not observable; therefore, count is a minimum estimate of ducks

[2] ca. 1975 most of Mildred Lake was converted into a tailings pond. Surveys in 2003 checked only the portion of Mildred Lake that remains in its natural state.

TABLE 3. Summary of oiled birds found at the Muskeg River Mine tailings ponds, April and May 2003.

Date	Common Name	Scientific Name	Group Size	Status	Oiled Status
26 April	goose spp.	unknown	1	Live	heavy – >80%
03 May	Common Goldeneye	*Bucephala clangula*	1	Live	heavy – 80%
19 May	Lesser Scaup	*Aythya affinis*	4	Live	light < 10%[1]
20 May	Bonaparte's Gull	*Larus philadelphia*	1	Live	heavy – 70%
21 May	small shorebird	*Calidris* spp.	1	Live	heavy – 60%
21 May	Lesser Yellowlegs	*Tringa flavipes*	1	Dead	moderate – 30%
26 May	Northern Shoveler	*Anas clypeata*	1	Live	heavy > 50%
26 May	Northern Shoveler	*Anas clypeata*	1	Dead	heavy – 100%
26 May	small Shorebird	unknown	1	Dead	heavy – 100%
26 May	medium passerine	unknown	1	Dead	heavy – 90%
26 May	large shorebird	unknown	1	Dead	heavy – 100%

[1] Lightly oiled but able to fly.

marginally non-significant ($P = 0.107$ and 0.105). To examine the apparent, though non-significant, effect of rainfall on birds being oiled, the cumulative rainfall was summed for the day of plus day before oiled birds were found and this had a significant effect (*Wald* = 4.973, d.f. = 1, $P = 0.026$) on the probability of birds being oiled. The positive coefficient of this variable indicated that the probability of a bird becoming oiled increased with higher rainfall. With the cumulative rainfall variable, the model was significant (*-2LL* = 30.264, *model* $\chi^2 = 5.636$, d.f. = 1, $P = 0.018$), but the model fit was weak (*Nagelkerke's* $r^2 = 0.212$, *Hosmer and Lemeshow test* $\chi^2 = 1.330$, d.f. = 1, $P = 0.095$). Small sample size likely contributed to the marginal significance of variables and the poor fit of the model, yet the persistence of rainfall effects indicate that precipitation was related to birds being oiled this year and this may be true more generally.

Discussion

Timing of Spring Migration

Although the radar system was not operational in April, visual observations suggested that migration activity in the study area was fairly low in April and early May and that migration peaked in mid-May. The radar was also not in operation (due to weather) for six days in May near peak migration (Figure 2); therefore, migration records presented here may have missed some critical portions of the migration. Nevertheless, the results on migration timing agree with other studies in northeastern Alberta. Richardson (1969) reported peak spring migration over east-central Alberta in May. Aerial surveys of lakes in this region during 1972 and 1973 reported peak numbers on 15 May and 25 May, respectively (SCL 1973). Likewise, Schick and Ambrock (1974*) showed peak migration to occur in middle and end of May in 1973. During aerial surveys in 1976/1977, Hennan and Munson (1979) reported peak spring migration for ducks in early May, with most abundant species being scaup (*Aythya* sp.), Ring-necked Ducks (*Aythya collaris*), Buffleheads (*Bucephala albeola*), and to a lesser extent Mallards (*Anas platyrhynchos*). Annual variation in timing of spring migration is likely to vary with timing of ice break-up of the Athabasca River and also the Peace-Athabasca Delta (Schick and Ambrock 1974*).

Although the timing of migration in northeastern Alberta is relatively well known, the composition and numbers of birds passing through the area are less well known. During the same time period of this study in 2003, Ronconi and St. Clair (2006) reported the following numbers of birds flying over the tailings ponds: 1140 ducks, 2132 shorebirds, 11 339 geese, 218 swans, 965 gulls, 56 terns and 205 others (loons, grebes, cranes, herons, cormorants, coots). These numbers give some indication of guild composition during migration but should be used cautiously as such because these were visual, daytime observations and many birds in Alberta migrate at night and at high altitudes (Richardson 1971; Blokpoel 1973; Blokpoel and Burton 1973). Hennan (1972) reported hundreds of thousands of waterfowl using the Peace-Athabasca Delta as a spring staging area, thus providing some indication of the volume of birds that may pass over the tar sands area each year. Nevertheless, many individuals of some waterfowl species may also take alternate migration routes to Alaska or nest in southern Canada (Miller et al. 2005).

Finally, in this study area we may also be observing resident as well as migratory waterfowl. This study makes no distinction between the two groups; however, the high proportions of northwesterly and northerly flights (Figure 2) suggest that most of the birds observed were migrants. It is likely that the small numbers of birds observed on the tailings ponds in May and on some lakes in late May were residents rather than stopover migrants. Surprisingly, the ecology of waterfowl at staging and stopover areas is fairly poorly understood (Arzel et al. 2006).

Numbers of Birds on Ponds and Lakes

Despite the apparent peak in migration around mid-May, the numbers of ducks on the tailings ponds peaked sooner than this. Working in a nearby area, Gulley (1980) found that duck dependence on tailings ponds was higher when spring ice break-up was delayed. In 2003, ice break-up on the nearby Athabasca River began 23 April and was finished by 1 May, yet many of the nearby lakes remained at least partially frozen through the first week of May. Duck surveys at Kearl Lake showed low numbers on 9 May when this lake was still partially frozen, but numbers grew by 23 times only one week later when the lake was ice-free. These results are mainly qualitative, but they support the hypothesis of others (Gulley 1980; D. Martindale, personal communication) that duck use of tailings ponds is highly dependent on the availability of open water elsewhere. After 9 May, duck numbers at the MRM tailings ponds were seldom above 10 individuals, while thousands of individuals were using Kearl Lake less than 20 km away. Nevertheless, these conclusions about seasonal change in dependence on tailings (early spring) to natural waterbodies (mid to late May) are tenuous due to several inconsistencies in survey methodology: (1) Kearl Lake was the only natural water body surveyed more than twice, (2) most natural waterbodies were surveyed only in late May and might have missed peak migration, and (3) lack of personnel did not allow for simultaneous surveys of tailings ponds and natural waterbodies. Bird movements between wetlands may have been a concern; however, the extremely low numbers of ducks at the tailings ponds after 7 May suggest little, if any, movement between artificial and natural ponds after this date. Finally, no data are available on wetland characteristics, which were beyond the scope of this project but may have had significant influence on waterfowl use of waterbodies.

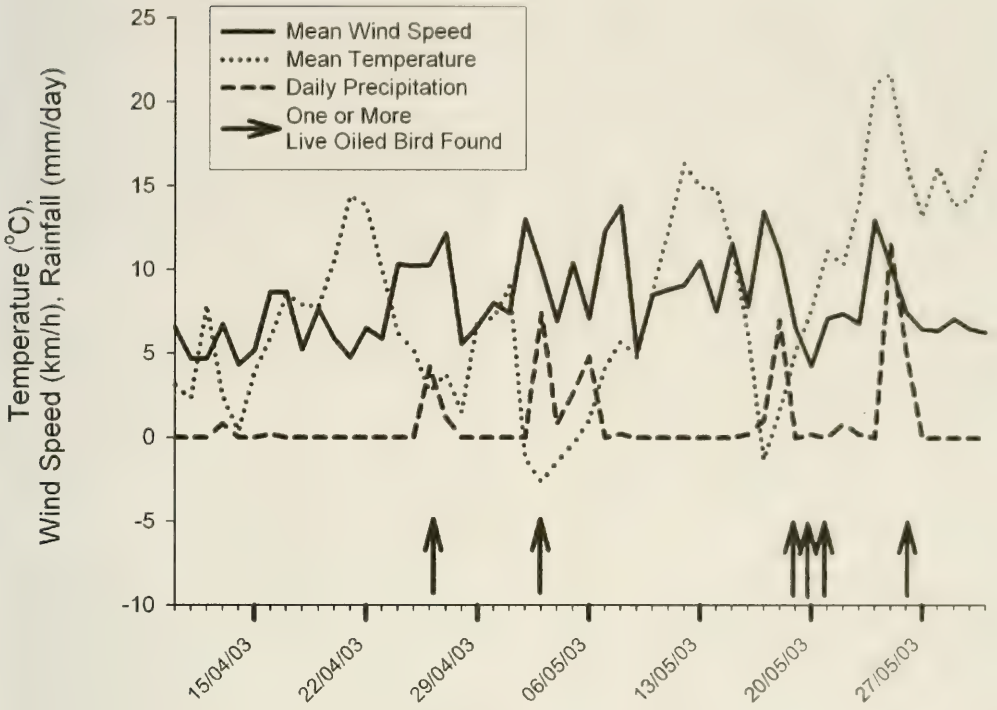

FIGURE 3. Weather patterns with respect to dates when live oiled birds were found at the Muskeg River Mine tailings ponds, April and May 2003.

Comparisons with census results from the 1970s suggest some changes in lake use. However, duck activity levels can vary widely within seasons, as was indicated in our results and other studies (e.g. SCL 1973; Gulley 1980; Van Meer and Arner 1985*; Shortt 1985*). The maximum counts between 1973 and 1977 were typically based on only one or two surveys during May, making them similarly prone to high variability. Although qualitative and tenuous, these comparisons reinforce the belief (SCL 1973; Schick and Ambrock 1974*; Ward et al. 1976*; Hennan and Munson 1979) that some lakes are important as stopover sites for migratory ducks, though not as major staging areas. As with our results, censuses from 1973 to 1977 ranked McCleland and Kearl lakes among the most important stopover sites for ducks (Hennan and Munson 1979). Other lakes in the region with high numbers included Little McCleland, Mildred, Horseshoe, and Saline lakes (Hennan and Munson 1979). The lack of ducks on Mildred Lake in 2003 is not surprising considering only a small portion of the lake remains in its natural state. The lack of ducks on remote lakes north of McCleland Lake was not surprising given the relatively small size of the lakes surveyed. Nonetheless, Hennan and Munson (1979) identified other remote lakes with high waterfowl densities, though these were not accessible for surveys by land in 2003.

Generally the oil sands region is not recognized as an important staging area for migratory waterfowl (SCL 1973; Schick and Ambrock 1974*; Ward et al. 1976*; Hennan and Munson 1979), although some staging does occur nearby. The Peace-Athabasca Delta, north of oil sands regions, has been recognized as an internationally significant staging area for hundreds of thousands of waterfowl (Hennan 1972). Further south of Fort McMurray, Gordon Lake was previously recognized as an important waterfowl staging area with spring numbers greater than 5600 in 1973 and 1974 (Hennan and Munson 1979). The count of 2700 waterfowl at Kearl Lake in 2003 suggest that this lake may bear greater importance as a staging area than might have been concluded from those earlier surveys, but further surveys may be needed to verify annual variation in waterfowl use of this lake. Surveys of other natural waterbodies also revealed that smaller ponds support small populations of birds throughout the spring and summer (Shortt 1985*). Because availability of natural waterbodies may minimize duck dependence on tailings ponds, further investigations of waterfowl use of these waterbodies is merited. Should it continue to appear that they are important to waterfowl, future oil sands developers may consider conserving these locations and avoiding the establishment of tailings ponds in close proximity to them.

Probability of Oiling

Logistic regression analysis of several weather variables found wind speed and precipitation to be the only variables that might predict the few observations of oiled birds in 2003. Strong winds may mix waters and spread oily films over wider areas, hence creating greater risk of oiling, but with consistent winds oily sheets may also be pushed to one shore of the pond. Thus any link between winds and oiling may be complicated. A two-day cumulative rainfall measure best predicted days with oiled birds, but rainfall the day of an oiling event and rainfall from the previous 24 hours showed some possible predictive ability. These uncertain results, along with small sample size, suggest only a potential effect of precipitation. Results of this study support a previous analysis across years (Gulley 1980) which showed that precipitation levels affected numbers of waterfowl deaths. Although Ronconi and St. Clair (2006) found no correlation between weather and bird landings on tailings ponds, the more important factor may be whether or not birds become oiled when they land.

If precipitation increases the frequency of birds being oiled, as these results cautiously suggest, I speculate that it may be caused by two possible mechanisms. First, poor weather conditions such as rain, strong winds, headwinds, and cold temperatures can delay migration, cause changes or a temporary reversal in migration direction, and cause migratory birds to be temporarily grounded (Richardson 1978; Elkins 1983). Waterfowl in particular appear to be erratic in their migratory behaviour which may be influenced by break-up of ice cover (Pöysä 1996), temperatures (Austin et al. 2002), weather fronts (Custer et al. 1997), and especially wind patterns (Bergman 1978; Liechti 1993; Bruderer 1994; Alerstam and Gudmundsson 1999). The significance of precipitation as a predictor of oiling may be due to correlations between rainfall and other weather changes, which may together be affecting bird movements and halting of migrations. The more frequently migratory waterfowl are forced to move and stop during migration, the greater the risk of encountering oil sands ponds and oil on the water surface in these ponds.

Second, precipitation may additionally increase oiling probabilities through birds experiencing reduced visibility during landings under rainy and snowy conditions. Without clear views of the water, they may be more likely to land in patches of oil which might otherwise be avoided. Reduced visibility as a causal mechanism may also explain the non-significance of wind speed, wind direction, and temperature since these variables should be less likely to affect the visibility of oil patches. Snow could affect in-flight visibility of birds, and on two of six days with oiled birds, the precipitation that occurred was a mix of rain and snow. Moreover, for three of the remaining days with oiling events (19, 20, and 21 May), heavy snow had fallen for two days previously (17 and 18 May). Although fog was not measured in this study, fog may also limit visibility and thus influence oiling events (Gulley 1980). Careful collection and thorough statistical analyses of long-term oiled bird records at tailings ponds may reveal important trends and weather association. These data could be valuable to improving the effectiveness of bird deterrent strategies, and I encourage oil sands companies to standardize collection protocols and pool their data for such an investigation.

Conclusions

As the development of oil sand mines continues in the 21st century, tailings pond and bird oiling problems will persist, and findings from current and previous studies will become more relevant to managers seeking a solution to this issue. Findings from this study suggest the importance of maintaining natural waterbodies in the region, especially those that are already used as migratory stopover sites for waterfowl. The significance of rainfall affecting numbers of birds being oiled suggests that bird deterrence efforts could benefit from enhancement on rainy days, and future deterrent development should pursue strategies that are effective during rainy weather more so than during clear conditions. With decades of data on oiled birds, and 30 years of research on bird deterrence, the oil sands industry in northern Alberta is positioned to offer significant insight into waterfowl management issues for future development here and at other sites of industrial development.

Acknowledgments

Logistical support and funding was provided by Albian Sands Energy Ltd., with additional logistical support from the University of Alberta, Edmonton. I thank Colleen Cassady St. Clair for support and guidance throughout this study and for reviewing drafts of this manuscript. I am grateful for support from Darrell Martindale, excellent field assistance from Andrew Forrest and Sarah Wong, and technical support from Will Neagle and Peregrine Systems Inc. Field work for this project was made possible with the help of Albian Sands employees Christine Theriault, Maurice Kay, Bob McKenzie, Thor Einarson, Brian Kean, and others on the Tailings and Site Services Teams. This manuscript was improved by comments from A. J. Erskine and one anonymous reviewer.

Hwang, Yeen Ten, and Serge Larivière. 2006. A test of interspecific effects of introduced Eastern Grey Squirrels, *Sciurus carolinensis*, on Douglas's Squirrels, *Tamiasciurus douglasii*, in Vancouver, British Columbia. Canadian Field-Naturalist 120(1): 10-14.

We compared the effects of absence and presence introduced Eastern Grey Squirrels (*Sciurus carolinensis*) on the demography of native Douglas's Squirrels (*Tamiasciurus douglasii*) in two urban parks in Vancouver, British Columbia: Ecological Reserve #74 in Pacific Spirit Regional Park (Douglas's Squirrel only) and Stanley Park (Douglas's and Eastern Grey squirrels). Based on the exploitative competition hypothesis, we predicted that in the presence of introduced Eastern Grey squirrels, Douglas's Squirrels would occur at lower densities, have larger home ranges, lower body mass, and poorer reproduction. Using mark-recapture methods, we found no differences in density, home range, or body mass of Douglas's Squirrel between parks. However, the proportion of breeding Douglas's Squirrels was higher in Ecological Reserve #74 in the absence of Eastern Grey Squirrel, than in Stanley Park. We found no evidence that Eastern Grey Squirrels are displacing Douglas's Squirrels in Stanley Park, but less conspicuous negative effects such as reduced breeding propensity may still reflect the competitive interactions of the two squirrel species.

Key Words: Density, home range, body mass, reproduction, Eastern Grey Squirrel, *Sciurus carolinensis*, Douglas's Squirrel, *Tamiasciurus douglasii*, exploitative competition, British Columbia.

In western Canada, Eastern Grey Squirrels (*Sciurus carolinensis*) were introduced to Stanley Park in the city of Vancouver, British Columbia, shortly before 1914. The three to four pairs of introduced Eastern Grey Squirrels came from eastern Canada (Robinson and Cowan 1954). In the early 1980s, Eastern Grey Squirrels colonized the rest of the city of Vancouver, including many of its urban parks. Since then, Eastern Grey Squirrels have spread to many parts of the Greater Vancouver Regional District (Gonzales 1999, 2000).

On the mainland in southwest British Columbia, the native tree squirrel is the Douglas's Squirrel (*Tamiasciurus douglasii*); it is the ecological counterpart of the Red Squirrel (*T. hudsonicus*) that is widespread in temperate forests of North America (Steele 1998, 1999). The Eastern Grey Squirrel is native in eastern North America (Hall 1981) and its geographical range overlaps broadly with that of the Red Squirrel. Although Red Squirrels are associated with conifer forests and Eastern Grey Squirrels with mast-bearing hardwood forests, the two species often coexist in mixed forests or urban parks (Riege 1991). Forty years after Eastern Grey Squirrels were introduced to southwestern British Columbia, Robinson and Cowan (1954) conducted a live-trapping and observational study on Eastern Grey Squirrels in Stanley Park. They noted that, in deciduous habitat in Stanley Park, Eastern Grey Squirrels lived at high densities together with lower densities of Douglas's Squirrels. They suggested that the Eastern Grey Squirrels outcompete Douglas's Squirrels for food, and thus restrict Douglas's Squirrels to areas of predominately coniferous habitat (Robinson and Cowan 1954). Whether competitive interactions between the two species still exist today (> 80 years since the introduction of Eastern Grey Squirrels) remains unknown.

In Great Britain, Eastern Grey Squirrels were introduced at the end of the 19th century, and have caused the decline of the smaller native European Red Squirrel (*Sciurus vulgaris*) from its former range (Gurnell and Pepper 1993; Wauters and Gurnell 1999; Teangana et al. 2000). The mechanisms of replacement of European Red by Eastern Grey squirrels are not yet fully understood (Skelcher 1997). Juvenile recruitment of European Red Squirrels is typically lower when Eastern Grey Squirrels are present (Wauters et al. 2000, 2001). Also, diseases such as parapoxvirus have been hypothesized to facilitate the replacement of European Red Squirrels by Eastern Grey Squirrels in the United Kingdom (Tompkins et al. 2003).

The Eastern Grey Squirrel averages 400–700 g in body mass (Koprowski 1984), and is larger than Douglas's Squirrel, which averages 250-300 g (Steele 1999). Douglas's Squirrels feed primarily on coniferous seeds, new shoots of conifers, green vegetation, acorns, nuts, mushrooms, fruits, and berries. Also, Douglas's Squirrels actively defend food middens within their territory

(Steele 1999). In its native range, the Eastern Grey Squirrel feeds heavily on hickory nuts, beechnuts, acorns, and walnuts (Koprowski 1984); however, introduced Eastern Grey Squirrels in British Columbia feed extensively on maple, oak, hazelnut, mushrooms, berries and pine cones (Robinson and Cowan 1954). Both species prefer seeds, and other plant foods predominate in the diet only when seed crops are small (Moller 1983). Also, in Stanley Park, a few Eastern Grey Squirrels depend almost entirely on "hand-outs" from park visitors as an artificial food source. Eastern Grey Squirrels living in close proximity to humans often venture out of the forests and feed on artificial food sources.

Eastern Grey Squirrels have a dominance hierarchy and are not territorial (Flyger 1955; Thompson 1977) whereas Douglas's Squirrels are territorial year round (Steele 1999). Territorial behaviour exhibited by Douglas's Squirrels is mainly used against conspecifics similar to Red Squirrels (Smith 1981). Intruding Eastern Grey Squirrels are generally free to enter their territory (Robinson and Cowan 1954).

The interspecific effects of the introduced Eastern Grey Squirrels on the native Douglas's Squirrels are unknown in southwestern British Columbia. We tested the hypothesis that Eastern Grey Squirrels negatively impact native Douglas's Squirrels through exploitative competition for resources. With the introduction of Eastern Grey Squirrels, resources such as food and nest sites in areas where both squirrels occur would decrease, causing an increase in home range size of Douglas's Squirrels because larger ranges are needed to collect more food (Schoener 1971). Larger home ranges would decrease the density of Douglas's Squirrels in the given area. Also, with increased home ranges, Douglas's Squirrels would expend more energy foraging and defending the area and would have less energy for reproduction and maintenance. Therefore, we predicted that in areas with Eastern Grey Squirrels, Douglas's Squirrels would occur at lower densities, have larger home ranges and lower body mass, and that they would reproduce less well.

Materials and Methods

We worked at two study sites. The species co-occur in Stanley Park, which was the original site of Eastern Grey Squirrel introduction to western Canada, and of Robinson and Cowan's (1954) study. The control study site was Ecological Reserve #74 (Pacific Spirit Regional Park) where only Douglas's Squirrels occur. Although Eastern Grey Squirrels do not occur in Ecological Reserve #74, they do occur in residential areas nearby and are abundant on the University of British Columbia campus only 1-2 km distant.

Both study areas are in the Coastal Western Hemlock biogeoclimatic zone. The dominant coniferous species in Stanley Park were Western Hemlock (*Tsuga heterophylla*), Western Redcedar (*Thuja plicata*), and Douglas Fir (*Pseudotsuga menziesii*). Stanley Park is a mosaic of second- (> 50 years old) and old-growth (> 120 years old) conifer stands. Ecological Reserve #74 represented a mature conifer stand (> 90 years old) with Western Hemlock, Western Redcedar, Douglas Fir, and Sitka Spruce (*Picea sitchensis*) with scattered Red Alder (*Alnus rubus*) and Big Leaf Maple (*Acer macrophyllum*). Understory and ground cover in both study areas consisted mainly of Vine Maple (*Acer circinatum*), Salmonberry (*Rubus spectabilis*), Red Huckleberry (*Vaccinium parvifolium*), Salal (*Gaultheria shallon*), leaf litter, ferns and mosses.

In each study area, we established a 9-ha live-trapping grid consisting of 96 (6 by 16) stations located at 30 m intervals. We set Tomahawk live-traps (model 201, Tomahawk Live Trap Co., Tomahawk, Wisconsin) at alternate trap stations, resulting in 48 traps per live-trapping grid. We live-trapped squirrels for 2 days every 2 weeks from May to August 1997 (9 trap sessions) in both study areas.

We baited the traps with sunflower seeds and set them in early morning and checked traps 4-6 hours later. Captured squirrels were ear-tagged with numbered metal tags (Monel #1, National Band and Tag Co., NewPort, Kentucky), sexed and weighed (± 5 g using a Pesola® spring balance). We noted breeding condition by palpation of male testes and female mammaries (Sullivan and Moses 1986).

We estimated population size, proportion of reproductive squirrels, body mass, and home range size. Population size and trappability were estimated for each trap session using the Jolly-Seber mark-recapture model (Jolly 1965; Seber 1965). We were not able to use radio-telemetry to estimate the territory size of Douglas's Squirrels in this study; therefore we estimated home range size by using trapping location for animals that were captured ≥ 2 times using the exclusive boundary strip method (Hayne 1949, 1950; Stickel 1954). Also, we only considered home ranges of females because in late spring and early summer, males roam extensively while searching for potential mates.

We used chi-square test to examine the trappability of squirrel populations between both sites. We used one-tailed t-test to compare densities of Douglas's Squirrels between sites. Due to unequal variances for Eastern Grey Squirrel densities in Stanley Park, we used Mann-Whitney U test to compare differences in densities between both species in the two study areas. We used two-way Analysis of Variance (ANOVA) to examine the difference in body mass and home ranges of Douglas's Squirrels between Ecological Reserve #74 and Stanley Park. The *Z*-test was used to test for significant differences in the proportion of squirrels in breeding condition (Sokal and Rohlf 1995). Since sample sizes of breeding individuals were small, the statistical power of the Z tests is very low in detecting

Table 1. Summary of demographic parameters for Douglas's Squirrels (DS) and Eastern Grey Squirrels (EGS) in Ecological Reserve #74 and Stanley Park, Vancouver, British Columbia, Canada from May to August 1997. Values shown are mean≠± SE.

	Ecological Reserve #74	Stanley Park	
	DS	DS	EGS
Density (individuals/ha)	3.5 ± 0.4	2.9 ± 0.1	2.5 ± 0.4
Home range (ha)	0.37 ± 0.096	0.44 ± 0.11	–
Trappability (%)			
Male	74.7	60.3	30.0
Female	80.9	74.0	30.0
Body mass (g)			
Male	181.8 ± 2.69	184.5 ± 3.81	608.6 ± 11.91
Female	177.4 ± 4.62	181.1 ± 4.40	603.7 ± 15.59
Proportion of breeding females (%)	20	5	77

a significant effect; however, the *Z*-statistic was used as an index of differences between study areas. All values are reported as mean ± SE.

Results

Density and home range

From May to August 1997, we captured 30 male and 24 female Douglas's Squirrels in Pacific Spirit Park. In Stanley Park, we caught 19 male and 25 female Douglas's Squirrels. Eastern Grey Squirrels were only found in Stanley Park, and we caught 22 males and 17 females. See Table 1 for a summary of demographic parameters.

Trappability of Douglas's Squirrels in Pacific Spirit Park was similar between males and females, at 74.7% and 80.9%, respectively. Male and female Douglas's Squirrels in Stanley Park also have relatively high trappability values, both ranging from 60.3% to 74.0%. On the other hand, Eastern Grey Squirrels had very low trappability, with males and females both having 30%. Trappability of Eastern Grey Squirrels was significantly lower in Stanley Park ($\chi^2 = 14.54$, df = 1, $P < 0.001$) than for Douglas's Squirrels.

Densities of Douglas's Squirrels did not differ ($t = 1.65$, df = 12, $P = 0.12$) between Ecological Reserve #74 (3.5 individuals/ha ± 0.4) and Stanley Park (2.9 individuals/ha ± 0.1). In Stanley Park, density also did not differ (Mann-Whitney T = 56, $P = 0.71$) between Eastern Grey Squirrel (2.5 individuals/ha ± 0.4) and Douglas's Squirrels (2.9 individuals/ha ± 0.1).

No effect of sex ($F_{1,64} = 0.18$, $P = 0.67$) or study area ($F_{1,64} = 1.24$, $P = 0.27$) on the home range of Douglas's Squirrels, nor were significant interactions detected ($F_{1,64} = 0.44$, $P = 0.51$). Home ranges averaged 0.31 ± 0.05 ha ($n = 96$).

Body mass and reproduction

No effect of study area ($F_{1,93} = 0.075$, $P = 0.78$) on body mass of Douglas's Squirrels was found, but there was a gender effect ($F_{1,93} = 5.41$, $P = 0.022$), with males (185.3 ± 4.1 g, $n = 48$) being heavier than females (177.2 ± 5.3 g, $n = 49$) in both parks.

For comparison purposes, Eastern Grey Squirrels in Stanley Park averaged 606.4 ± 19.1 g with no gender difference ($t = 0.25$, df = 37, $P = 0.80$). On average, male Eastern Grey Squirrels weighed 608.5 ± 11.9 g, and females weighed 603.8 ± 15.6 g.

From 20 May to 28 August 1997, proportions of female Douglas's Squirrels in breeding condition differed significantly between sites ($Z = 2.56$, $P < 0.001$), with a higher proportion of breeding females in Ecological Reserve #74 compared to that in Stanley Park: 20% (15 breeding out of 77 individuals) and 5% (3/62), respectively. In Stanley Park, the proportion of female Eastern Grey Squirrels in breeding condition (77%: 17/22) was higher than for Douglas's Squirrels (5%: 3/62). However, the proportion of breeding male Douglas's Squirrels at the two sites was similar and averaged 98.3% (59/60).

Discussion

We did not detect strong effects of exploitative competition between Eastern Grey Squirrels and Douglas's Squirrels. There was no evidence of reduced density, large ranges, and lower mass in Douglas's Squirrels where the two species co-occurred. However, the proportion of breeding Douglas's Squirrels was significantly lower in Stanley Park compared to that in Ecological Reserve #74, suggesting possible negative effects of Eastern Grey Squirrels on the breeding propensity of Douglas's Squirrels.

Densities of Douglas's Squirrels are limited by food availability (Sullivan and Sullivan 1982; Ransome and Sullivan 1997), and old-growth forests provide higher-quality habitat for Douglas's Squirrels than younger forests due to greater and more reliable quantities of conifer seed (Buchanan et al. 1990). In our study, the densities of Douglas's Squirrels were similar at both sites, suggesting that habitat suitability was similar, and further suggesting that reduced breeding propensity was caused by the presence of Eastern Grey Squirrels, and not simply an artifact of difference in food availability among study areas.

A possible explanation for weak effects of exploitative competition between the two species of squirrels could be due to the fact that Eastern Grey Squirrels often can exploit broadleaved and deciduous wood-

land to increase breeding success by feeding on high-energy food (Skelcher 1997; Gurnell et al. 2001), but since both study areas consist of mixed woods with high conifer content, advantages in breeding success of Eastern Grey Squirrels were perhaps less pronounced (Teangana et al. 2000). Thus, Douglas's and Eastern Grey Squirrels could coexist for many years although perhaps Douglas's Squirrel would slowly decline due to lower reproductive outputs (Reynolds 1985; Gurnell 1996).

Our density estimates for Eastern Grey Squirrels (2.5 individuals/ha) also were slightly higher than those reported >45 years earlier (1.7 individuals/ha; Robinson and Cowan 1954), suggesting that the population of Eastern Grey Squirrels in Stanley Park is relatively stable, even if their range elsewhere has expanded (Gonzales 1999, 2000). If the combined presence of both Douglas's and Eastern Grey squirrels in Stanley Park accelerates the depletion of the autumn seed crop, this might force a greater dependence on alternative plant foods in the spring and summer, which Eastern Grey Squirrels are better able to use because of their larger body size (Ackerman and Weigl 1970; Steele and Weigl 1993). An investigation into the feeding behavior and space use of both species would provide a better understanding of how Douglas's and Eastern Grey squirrels coexists in anthropogenic environments such as urban parks. This study highlights the need for more long-term population monitoring of the interaction of the two squirrel species in areas where Eastern Grey Squirrels were introduced.

Acknowledgments

Douglas Ransome and T. P. Sullivan helped design the study and provided valuable insight, statistical help and field equipment. Many thanks to Mike Mackintosh (Wildlife Manager, Vancouver Parks Board) and Greg Paris (Wildlife Manager, Greater Vancouver Regional District) for permission and help with study area design. J. N. M. Smith reviewed an earlier draft of this manuscript.

Nol, Erica, Hume Douglas, and William J. Crins. 2006. The response of syrphids, elaterids and bees to single tree selection harvesting in Algonquin Provincial Park, Ontario. Canadian Field-Naturalist 120(1): 15–21.

The species composition of hoverflies (Syrphidae), click beetles (Elateridae), and bees (Apoidea) was studied to determine whether there was a positive response in these flower-seeking insect groups to gaps in the canopy created through single tree selection harvesting of Sugar Maple (*Acer saccharum*) and Yellow Birch (*Betula alleghaniensis*) in hardwood forests of the Great Lakes-St. Lawrence forest region of Algonquin Provincial Park, Ontario. There were significantly more hoverflies and bees collected in forest stands harvested within the previous five years than in wilderness zone (unharvested at least for 40 years) stands or stands harvested 15-20 years previously (old logged stands). Click beetles, especially *Selatosomus pulcher* (LeConte), were collected most often in old logged stands. Bees and click beetles were collected significantly later in the season in logged than in wilderness zone stands. Malaise traps resulted in higher capture rates for syrphids than pan traps, and only with these higher capture rates did we detect a significant increase in species richness in recently logged stands over that in wilderness stands. Changes in the numbers and phenology of flower-visiting insects may impact on reproductive success of flowering plants of the forest understory and deserves further study.

Key Words: single-tree selection logging, syrphids, hoverflies, Syrphidae, click beetles, Elateridae, bees, Apoidea, Algonquin Provincial Park, hardwood forests.

Single-tree selection harvesting[†] in shade-tolerant hardwood forests creates cyclic perforations in the canopy on a 20-25 year rotation and is hypothesized to simulate conditions found under gap-phase dynamics. This form of silviculture is practised in many parts of the Great Lakes-St. Lawrence Forest Region in Ontario and Quebec (Hunter 1990). Very little is known about the impact on non-target species of removing 25% of the basal area of the forest through selection cutting (Annand and Thompson 1997).

Particular invertebrate groups are most likely to respond to changes in light conditions of the forest floor as a result of reductions in canopy cover. Many plants respond positively to increased light. As a result, insects with adult stages attracted to conspicuous flowers, also are expected to increase in abundance. These include bees (Hymenoptera: Apoidea), hoverflies (Diptera: Syrphidae), a family of flies that contains important flower visitors and pollinators (Waldbauer 1983; Kula 1997; Goulson and Wright 1998; Gross 2001), and many click beetles (Coleoptera: Elateridae), a less well-known group of flower visitors (Johnson 2002).

Changes in other components of the forest as a result of selection cutting may also benefit these insects. Larvae of hoverflies of the subfamily Syrphinae feed largely on aphids (Vockeroth 1992), and may benefit from increased herbaceous growth associated with canopy opening. Larvae of many elaterids (Johnson 2002) and some hoverflies of the subfamily Eristalinae (Vockeroth 1992) inhabit decaying wood. Their response to logging may depend on the availability of amounts, sizes and decay states of the standing and fallen trees remaining after each phase of the logging cycle. Soil-inhabiting elaterid larvae and ground-nesting bees may be affected by changes in vegetation, litter composition and depth, microclimate, and soil disturbance (Penev 1992; Sugar et al. 1998). Disturbance caused by construction of sand logging roads may result in greater colonization by psammophilous bees and elaterids in a previously unsuitable forest stand (Cane 1991).

We studied the impact of selection cutting on these non-target invertebrates in Algonquin Park, Ontario. We predicted positive density responses for all three groups, either as a result of an increase in spring flora, or other changes associated with logging. We also predicted that the presence of insects that visit flowers would extend later into the growing season in logged forests than in unlogged stands because of the greater amount of light penetrating to the forest floor throughout the spring and summer seasons. We tested these predictions by comparing these insect communities in

[†] Under *selection harvesting*, only some of the trees are cut in order to balance the volume of wood harvested with the amount produced through new growth and to enhance biodiversity and ecological functions. This system of silviculture differs from *selective harvesting* in which only the best timber trees are cut and the forest is gradually degraded.

stands cut 6 months to 3 years before our sampling, 15-20 years before, and in stands that have not been subjected to logging for at least 40 years.

Study Area and Methods

The study was conducted in the summers of 1997 and 1998 in Algonquin Provincial Park, Ontario (42°32'N, 78°36'W), as part of a larger study that was examining impacts of logging on birds (Jobes et al. 2004) and ground beetles (Carabidae: Vance and Nol 2003). Forest stands were chosen randomly (within the constraint that they be within 500 m of road access) in wilderness designated zones (Algonquin Park Management Plan 2000), last logged at least 40 years prior to survey), old logged (15-20 years post cutting), and recently logged (6 months – 3 years post cutting) areas. Canopy cover (estimated in July) ranged from 60-70% in the wilderness zone to 25-35% in old cut and recently cut stands, and was significantly higher in the wilderness zone stands than in both the old logged and recently-cut stands (Jobes et al. 2004). Other vegetation differences included a significant increase in vegetation under 2 m and percent logging residue cover (mostly tops of trees) in the recently cut stands over that in the other two treatments, and a significant increase in stem densities and saplings (2-5 m) and subcanopy (5-10 m) vegetation in the old logged treatments as compared to the other two (Jobes et al. 2004).

In 1997, we used a single Malaise trap set on a ridge in one stand of each of the recently logged and wilderness zone treatments. It was emptied at 1-week intervals every other week from May to August. Thus, we had no replication of stands for this year. In 1998, we set yellow pan traps (21 $cm^2 \times 5$ cm depth) filled with water to a depth of 2-3 cm, and a small amount of detergent in a total of 18 stands. These traps were set, within stands, at 100 m intervals at permanent markers. We sampled eight stands in the wilderness zone, seven in the recently logged areas, and three in the old logged areas. Stands were separated by a minimum of 200 m, but most stands were separated by > 3 km, in stands consisting of at least 75% upland deciduous forest (Vance and Nol 2003) so we assumed that they were spatially independent. Each stand contained a minimum of three traps. The sampling was uneven in the treatments because of accessibility of stands and because two of the initial old logged treatments were logged in the winter of 1997-1998. These traps were set from early May to late August, and emptied weekly for three weeks in early, mid, and late summer periods, for a total of nine trapping weeks. There were 69 incidents of trap disturbance by mammals.

Pitfall traps were used to obtain activity-density estimates for click beetles (Baars 1979). Pitfalls were constructed using 1 litre plastic 11.5 cm diameter containers lined with 500 mL plastic containers of the same diameter (Spence and Niemelä 1994). The traps were dug into the ground so that the top of the upper container was level with or slightly below the surface of the soil. Each trap was filled with approximately 300 ml of water, with a few drops of dish soap added to reduce surface tension. Two pitfall traps were set at 4 m to each side of the permanent stand markers, at the same intervals as the pan traps. In 1997, pitfalls were set for one week in each of May through August for a total of four weeks. In 1998, pitfalls were set for the same periods as the pan traps. A small number of traps (5%) were disturbed in all treatments

All invertebrates were sorted initially to class, and all but insects were discarded. Insects of the three target groups were then sorted and identified with the use of keys by Becker (1956, 1974); Brown (1934); Coovert and Thompson (1977); Curran (1921, 1922, 1925, 1934, 1941); Curran and Fluke (1926); Dietrich (1945); Fluke and Hull (1945); Fluke and Weems (1956); Hull and Fluke (1950); Michener et al. 1994; Mitchell (1960); Shannon (1939); Telford (1970); Vockeroth and Thompson (1981); and Vockeroth (1992). Voucher specimens are deposited in the Canadian National Collection of Insects and Arthropods, Agriculture and Agri-food Canada, Ottawa.

As we began sampling in all treatments at the same time, we used the dates (1998 only) on which the target groups were captured as independent samples, for our comparisons of phenology. These data were highly skewed so we used the Kruskal-Wallis ANOVA to test for significance among treatments. We were unable to use stands as sampling units for any statistical comparisons because capture rates were too low. Thus, we tested for significant differences among treatments in species and numbers of individuals trapped, using chi-square tests, with proportion of total trapping effort among treatments used to calculate expected numbers. We report standardized residuals ((Observed – Expected)/ √Expected) and their direction to show which treatment had greater or less than the numbers of individuals or species than expected based on our sampling effort (Quinn and Keough 2002). For pitfalls and pan traps we usually caught single individuals of the target species and these were spread across a range of stands within that treatment, so that the assumption of independence for this statistical test was probably not violated (i.e., the samples are not biased by many individuals caught in one particular stand and treatment except in cases where noted below). Given the low capture rate for any of our target groups we did not calculate or analyse patterns of diversity.

To assess spring ephemeral abundance, we counted, in 1 m^2 quadrats placed 5 m to the side of pitfall and pan trap locations, all visible stems of spring-blooming forb species during the first sampling period in May 1998, before canopy leaf emergence.

Results

Each of the three target groups had substantially higher captures per unit effort (combining sample across all stands per treatment because of low num-

bers captured) in at least one logged treatment than in the wilderness zone treatment (Table 1).

Syrphids. In both years, with both pan and malaise trapping methods, more species of syrphids were caught in logged than in unlogged landscapes (Table 2). In 1997, eight species were found in wilderness zone malaise traps and 25 species were trapped from the recently logged stands with three species in common between the two treatments. As Malaise traps were opened for an equal number of days in the two stands, we calculated expected numbers using the binomial distribution, based on $P = 0.5$. Significantly more

TABLE 1. Catch per unit effort (×100) for all Syrphidae, Elateridae and Apoidea caught in pan traps in recently logged, old logged, and wilderness stands in 1998, and combined catch for pitfalls in 1997 and 1998.

	Recently Logged	Old Logged	Wilderness
Total pan trap days	1894	1040	2961
Total pitfall days	4796	3088	7938
Syrphidae (pan)	0.68	2.31	0.17
Elateridae (pan)	1.37	6.82	3.71
Elateridae (pitfall)	0.27	1.49	0.30
Apoidea (pan)	3.22	2.11	1.28

TABLE 2. Species and numbers of individuals captured of Syrphidae from pan traps set in recently logged, old logged, and wilderness stands in Algonquin Provincial Park using Malaise traps in 1997 and pan traps in 1998. χ^2 statistic provided for test of association between number of individuals and species and logging treatment. Standardized residuals give direction and strength of deviation (Quinn and Keough 2002)

syrphid individuals and species were captured in the Malaise trap set in the recently logged than in the wilderness habitat (Binomial test, species: $P < 0.0001$, individuals: $P < 0.0001$). In 1998, using pan trap catches, two species, each consisting of one individual each, were found only in the wilderness zone, whereas nine species were found only in the recently logged landscape. Only six species were found in both years using the two capture techniques. Significantly more individuals were caught in 1998, in the old logged stands than in either the recently logged or wilderness treatments (Table 2), but this result was entirely due to a capture of 17 individuals of the species *Melanostoma mellinum* on 14 May 1998 in the old logged treatment.

In 1997, we did not begin sampling until late May, after leaf-out in the park. In 1998, there was a strong bias in the collection times for all syrphids, with 16 of 22 collection dates for syrphids (73%) in May, prior to leaf-out. There was, however, no significant difference among treatments in the collection dates of syrphids in 1998 (median sample dates (range): wilderness: 29 May (26 May-6 August), $n = 5$ trap sample dates; old logged: 21 May (14 May-2 July), $n = 4$; recently logged: 27 May (9 May-24 June), $n = 13$, Kruskal-Wallis $\chi^2 = 4.33$, $P = 0.11$).

Bees. Twelve species of bees were identified, with five of these from wilderness and old logged stands and all twelve in the recently logged stands (Table 3). All but four species (excluding *Andrena*) were halictids. For both number of species and number of individuals the recently logged stands had significantly more bees than expected based on catch effort (Table 3).

All but 6 of the 57 dates on which we captured bees were in May. Bees were caught at a significantly later date in recently logged stands than in either old logged or wilderness stands (median collection dates (range): wilderness: 10 May (8-20 May), $n = 18$ trap sample dates; old logged: 9 May (9 May-24 June), $n = 13$; recently logged: 19 May (9 May-14 July), $n = 26$, Kruskal-Wallis $\chi^2 = 13.8$, $P < 0.001$).

Elateridae. In this group of insects, two species, *Ctenicera triundulata* and *C. vulnerata* were found only in the wilderness stands, both in very low numbers (Table 4). The number of species among treatments did not deviate from expected using the pan trap data but was marginally higher than expected in the old logged treatment using the combined 1997/1998 pitfall data (combined years due to small sample sizes, $\chi^2 = 5.89$, $P < 0.06$).

Numbers of individual click beetles were significantly higher in the old logged habitat, and significantly lower in the wilderness zone than expected based on catch effort, using pan traps and pitfall traps (Table 4).

Elaterids were collected in 1998 from pan traps at significantly later dates in old logged and recently logged stands than in wilderness zone stands (median date (range); wilderness zone: 13 May (8 May-5 June), $n = 9$; old logged: 28 May (8 May-9 July), $n = 23$; recently logged: 19 May (9 May-2 July), $n = 23$; Kruskal-Wallis $\chi^2 = 7.6$, $P = 0.02$). Using 1998 pitfall data, elaterids were sampled significantly later in recently logged stands than in the other two treatments (wilderness zone: 17 May (13 May-4 August), $n = 20$; old logged: 17 May (14 May-3 July, $n = 22$; recently logged: 24 June (12 May-24 June), $n = 9$; Kruskal-Wallis $\chi^2 = 6.34$, $P = 0.04$). The 1997 elaterid data were too sparse for analysis.

Spring ephemerals. We recorded 15 species of spring ephemerals in our quadrats (1998 only). The numbers of ephemerals found in all of the stands were extremely variable (cv's range from 156-165%). Although the mean number of stems in the recently logged stands was more than twice as large as this number in wilderness zones, there was no significant difference among treatments (recently logged: 59.7 ± 16.7 / m^2, $n = 23$ plots; old logged: 46.5 ± 22.1 / m^2, $n = 13$ plots; wilderness zone: 26.5 ± 18.8 / m^2, $n = 18$ plots; $F_{2, 51} = 0.88$, n.s.).

Discussion

Our results suggest that all three of groups of flower-visiting insects were more abundant in one of the logged habitat types than in the wilderness zone. This suggests that these insect groups were positively affected by single-tree selection harvesting as it is practised recently and/or how it was practised in the 1970s, when the selection cuts were heavier than is currently acceptable (Algonquin Forestry Authority, unpublished). This result is not explained simply by greater numbers of spring ephemerals, as, at least with our sampling methodology, we found no significant difference among treatments in the availability of flowers measured prior to leaf-out. Differences were apparent in number of individual insects, but, in general, not in insect species richness, except in the case of the Malaise traps set in 1997, where both numbers of individuals and species richness were higher in collections from the trap in the recently logged stand. Given that this result is for one trap only in each treatment, this result should be viewed cautiously.

As many larval syrphids prey on Homoptera in herbaceous vegetation and many adults feed on nectar sources in this vegetation, the presence of much higher percent cover of herbaceous or soft woody vegetation (37 to 43% in old logged and wilderness stands respectively, to 78% in recently logged stands, particularly *Rubus idaeus* L. var. *strigosus* (Michx), Jobes 1999) could explain the significant increase in syrphid abundance that we found through Malaise trapping. An apparent increase also was noted in our pan trapping results but not established statistically because of the generally poor success of this method for capturing syrphids in any of our stands. A similar positive numerical response in syrphids (also not tested statistically) was found in Poland's polluted spruce forests,

as an apparent result of drastic reductions in canopy cover and greater herbaceous and grass undergrowth (Kula 1997). Some species of at least two genera of hoverflies that were found in the wilderness zone (*Melanostoma* and *Platycheirus*) specialize on graminoid and other anemophilous pollen, enabling them to be active later into the spring/summer when graminoids typically flower (Vockeroth 1992; Gilbert 1993). However, none of the species captured is restricted to flying in the spring.

Bees, like syrphids, were most abundant in the recently logged areas. Unlike syrphids, larval bees are fed pollen and thus are more wholly dependent on floral resources. Some bees also may be affected by the

availability of open flight paths present in the open understory of the recently logged treatments, to make pollen-gathering trips for brood provisioning, although the effects of forest habitat on bee movement is probably species-specific, and for many species these movement patterns are unknown (Kreyer et al. 2004). Woodland and edge ground nesting bees (the majority of the species caught in the recently logged stands) are thought to benefit from patches of disturbed habitat associated with habitat fragmentation (Cane 1991) and thus, may benefit from the building of sand logging roads. Halictid bees can be major components of pollinator communities in other forest types (Pascarella 1997). Their role in northern hardwood forests has not been adequately assessed.

Elaterids were most abundant in the old logged habitats, using two methods of sampling, indicating positive responses to the much higher cover of the sapling (2-10 m) layers found in this treatment (Jobes et al. 2004). The most abundant species, *Selatosomus pulcher*, has been trapped in open field habitats (Boiteau et al. 2000). This species is morphologically nearly indistinguishable from the European species *C. cruciatus*, a species whose larvae develop in the sandy and moist soils in forest and forest edge (Leseigneur 1972). The higher abundance of elaterids in the old logged treatment areas may be due largely to this species' positive response to the edge-like conditions present in this treatment. The lower numbers of elaterids in the recently logged stands may indicate the absence of colonization because of the short time frame. Analagous results are suggested in a study of herbaceous plants in recently logged White Pine (*Pinus strobus*) stands in Algonquin. Plants in those stands were most similar to plants in unlogged stands presumably because there had been insufficient time for changes in community assemblages after the logging (Kingsley 1998).

As little is known about the role of adult food availability in the distribution of elaterids, the near significant positive effect on species richness may also be due to the greater availability of soil invertebrates or plant material suitable for larval food produced by a four-fold increase in the number of stumps in old logged versus either wilderness or recently logged stands (Jobes 1999).

Of the two elaterids caught only in the wilderness treatment, only one may be an old growth dependant species. *Ctenicera vulnerata* (1 specimen caught) has rarely been collected, and has not been reported previously from Ontario. The other, *Ctenicera triundulata* (2 specimens) cannot be considered old growth-restricted, as it has been collected in moderate numbers in an apparently healthy spruce (*Picea* sp.) in an old field by HD.

We found very few bees, syrphids or click beetles in our samples from the wilderness zone stands, although we expected to find some, at least early in the season when the canopy had not yet leafed out or of species that utilized downed woody debris (e.g., *Chalcosyrphus*, *Xylota*, *Brachyopa*). The reason for their paucity in the wilderness zone is unclear but deserves further study.

The numerical increase and changes in phenology of flower-associated insect species suggests the potential for greater pollinator efficiency in logged forests, and hence greater reproductive success, through greater seed set of flowers. A more detailed examination of species-specific patterns of habitat use by pollinators and their functional role in hardwood forests is worthy of future research (e.g., Sheffield et al. 2003; Kreyer et al. 2004).

Acknowledgments

We thank, in particular, Christine Vance, who tirelessly emptied pan traps in 1998 for this project. We also thank Andrew Jobes for collecting some of the data on spring ephemeral abundance and providing the canopy cover information. We thank E. C. Becker for verifying elaterid identifications, and R. Tuckerman, J. Grixti and T. Romankova for identification of bees. D. Voigt and E. Addison provided the stimulus for this project through their project on disturbance of ecosystems in Algonquin Park. We thank them for their extensive logistic support. The Algonquin Forestry Authority (AFA) also provided details on the history of the stands. N. Quinn (Algonquin Park) kindly provided funding for our work on birds and beetles in the park. This project was also funded by NSERC (Canada) grants to E. Nol.

New Nesting Records of the Le Conte's Sparrow, *Ammospiza leconteii*, from Northeastern Ontario, with Some Notes on Nesting Behaviour

MICHAEL PATRIKEEV

Ontario Parks, 199 Larch Street, Suite 404, Sudbury, Ontario P3E 5P9 Canada
Present address: 3 Helen Street, Dundas, Ontario L9H 1N2 Canada; e-mail: mpatrikeev@hotmail.com

Patrikeev, Michael. 2006. New nesting records of the Le Conte's Sparrow, *Ammospiza leconteii*, from northeastern Ontario, with some notes on nesting behaviour. Canadian Field-Naturalist 120(1): 22–26.

Le Conte's Sparrow is sparsely distributed through northeastern Ontario with no confirmed records from Algoma District and eastern Lake Superior. Two nests were found in open poor fen between Wawa and Hawk Junction in central Algoma District in 1999. Notes on behaviour, nests, nestling development and feeding effort were taken during 9 hours and 38 minutes at one nest over three days.

Key Words: Le Conte's Sparrow, *Ammospiza leconteii*, nesting, northeastern Ontario.

Le Conte's Sparrow (*Ammospiza leconteii*) is distributed through grasslands and wetlands of central and southern Canada east to Ontario and Quebec, and in the north-central United States. "It is one of the least known North American sparrows and any new information on this species may be of interest" (Lowther 1996). A cryptic species, it nests in thick clumps of dead grass, and its nests are difficult to find. Only about 50 nests had been recorded range-wide by the early 1960s (Walkinshaw 1968) and few have been documented since then (Lowther 1996). Only nine nests of this species had been found in Ontario prior to 1999 (Peck and James 1987; Sandilands and Campbell 1987; G. Peck, personal communication). In Ontario, Le Conte's Sparrow has been reported in widely separated areas in the forest zone with the greatest concentrations in the James Bay Lowland and northwestern Ontario (Sandilands and Campbell 1987). During the first Ontario Breeding Bird Atlas (1981-1985) this species was found in only 20 of 137 UTM blocks (100 × 100 km) and nesting was confirmed in only four blocks (Sandilands and Campbell 1987). None of the first Atlas records were from Algoma District, although Le Conte's Sparrow was considered a rare spring species in the vicinity of Wawa (Ontario Ministry of Natural Resources 1990). In 2001-2004, surveyors for the second Ontario Breeding Bird Atlas reported probable nesting in two blocks (Sault Ste. Marie and St. Joseph Island), and possible nesting in five additional blocks in the vicinity of Sault Ste. Marie and Thessalon at the south end of Algoma District (Ontario Breeding Bird Atlas website: http://www.birdsontario.org/atlas).

Here I describe two new nests from central Algoma District, northeastern Ontario. A small group with 2-3 singing males was found in an upland wetland (5.8 ha, 48°02'42.24N", 084°34'01.30W") in Esquega Township east of Wawa and southwest of Hawk Junction (Figure 1). The wetland (329 m above sea level) encompassed elements of several wetland types gradually changing from sphagnum bog with few stunted Black Spruce (*Picea mariana*) to open poor fen and then to a meadow marsh (Harris et al. 1996).

Le Conte's Sparrows inhabited approximately 2 ha of open poor fen in this wetland (see Figure 2). The wetland was bordered by alder thickets (Speckled Alder, *Alnus incana*) with a few dead Balsam Poplars (*Populus balsamifera*) and by mixed forest dominated by Trembling Aspen (*P. tremuloides*) and White Birch (*Betula papyrifera*). Water regime of the wetland changed from late May through July 1999. The lower parts (mostly meadow marsh section) were flooded in late May (up to 0.5 m deep), but water gradually receded by late June. The area remained damp, but no standing water remained (natural flow in this wetland was likely disrupted years ago when it was transsected by Highway 101). The area occupied by Le Conte's Sparrows had a ground cover of sphagnum moss and was dominated by two species of sedge: Few-seeded Sedge (*Carex oligosperma*) and Awl-fruited Sedge (*C. stipata*); Canada Bluejoint (*Calamagrostis canadensis*) was also present.

Singing males were heard at the wetland on 21 May 1999, and a display flight observed on 27 May. A flight song is described by Murray (1969). I also observed a "spy flight": a sparrow would rise from the grass and fly in a low arch quickly dropping back into the cover. Le Conte's Sparrow likely uses this flight to determine precise position of an approaching intruder. No song or audible call was uttered during such flight.

Two nests were found in the wetland, on 13 June and 17 July 1999, respectively. The first nest contained five eggs (Figure 3), but was empty on 17 June. The eggs matched a description of Le Conte's Sparrow eggs from Walkinshaw (1968). The second nest contained five newly-hatched young on 17 July and still contained five young on 23 July when the young would be seven days old. On day seven, the young were in cinnamon-coloured plumage with dark streaks on the back, dark

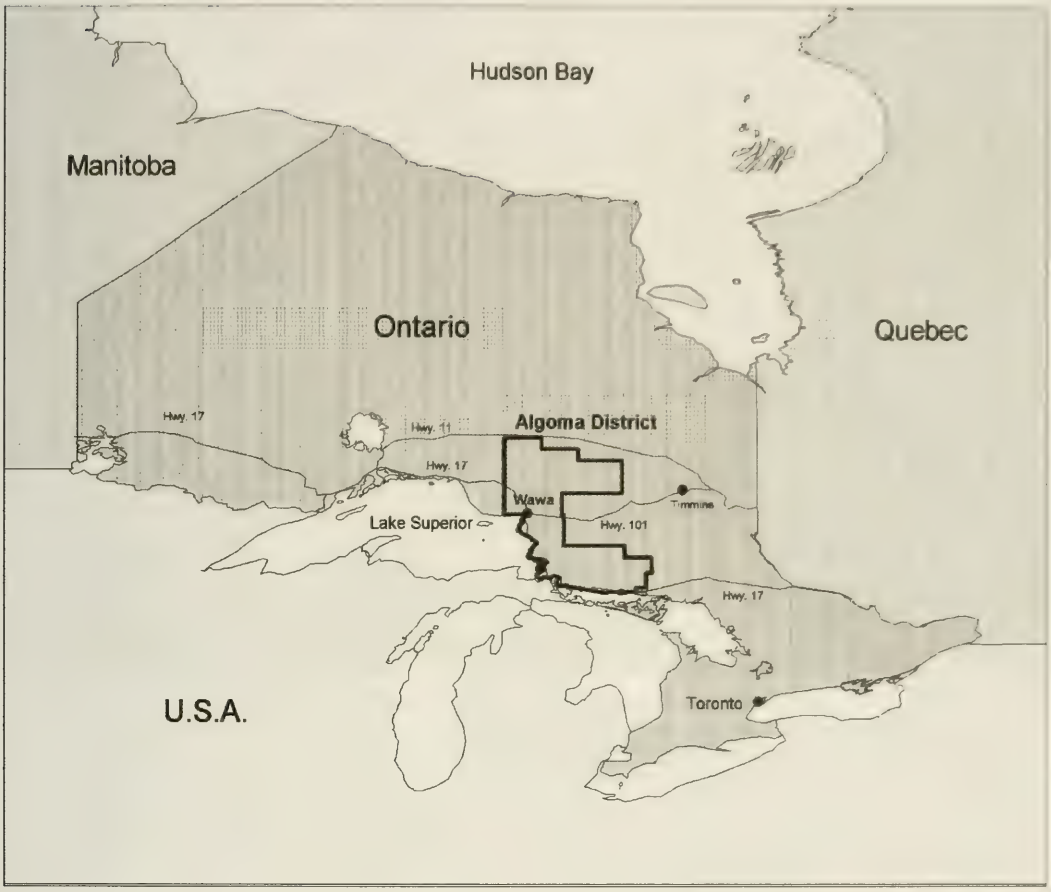

FIGURE 1. Position of Wawa and Algoma District in Ontario.

grey crowns and cheeks, tan median crown-stripe and black shafts. The median crown-stripe was seen in at least some chicks (Figure 4). Bill colour changed from fleshy on days two-three to grey-pink on day seven. Gape was bright flesh red on day seven. According to Gollop et al. (1966), the young leave the nest at the age of seven days.

The two nests were approximately 150 m apart and might have belonged to the same pair. Both nests were built of dried stems, and lined with fine dried stems of sedge and grass. Outer rim of both nests was loosely built. The first nest was well hidden under and inside a clump of dried graminoids and could not be seen from above. The second nest was attached to dried and living sedge stems and a small Leatherleaf (*Chamaedaphne calyculata*) under a loose cover of sedges and grasses. Both nests were 5-6 cm above the wet ground.

Observations totaling 9 hours and 38 minutes were made at the second nest from a blind (through a telephoto lens) during late afternoon-early evening hours on 19 July (1610-2045 hours), 21 July (1800-2110) and 22 July (1812-2005). All observations were conducted during calm fair weather. The pair at the nest under observation consisted of a slightly larger brighter male, and a scruffier duller female. Le Conte's Sparrows never flew directly to and from the nest, but landed some distance away and walked (hopped) to it, fed the young and walked away before taking on the wing. Also both birds were never present at the nest at the same time during the observation period. A total of 80 feeding visits was recorded. The birds were bringing food every 6.6 minutes on average (SD ± 5.2, Standard error 0.6). Lowther (1996) reported 1 feeding/minute at a nest containing a cowbird. Gender of feeding birds was assumed on 55 occasions. The male fed the young on average every 14.1 minutes (SD ± 13.5) and the female every 13.5 minutes (SD ± 13.5). No differences between sexes were detected in feeding efforts ($P = 0.50$). Intervals between feedings became shorter as the young were growing: every 7.9 minutes ± 5.9 on 19 July, 5.7 ± 4.6 on 21 July and 4.9 ± 3.0 on 22 July (Kruskal-Wallis one way ANOVA: $P = 0.07$).

FIGURE 2. Habitat of Le Conte's Sparrow in Esquega Township: this wetland encompassed elements of several wetland types gradually changing from a sphagnum bog to open poor fen and then to a meadow marsh. Le Conte's Sparrows inhabited about 2 ha of open poor fen. Photo by Michael Patrikeev.

FIGURE 3. Nest of Le Conte's Sparrow with five eggs. The nest was built of dead stems, and lined with fine stems of sedge and grass. It was well hidden under and inside a clump of dead graminoids and could not be seen from above. Photo by Michael Patrikeev. 13 June 1999.

FIGURE 4. Nestlings of Le Conte's Sparrow seven days old. Photo by Michael Patrikeev. 23 July 1999.

Lowther (1996) noted that hardly any information was available on this species' diet. Although in many cases food brought to the young was too small to identify through a telephoto lens, I observed small green caterpillars, a white moth, a spider, a small sphinx caterpillar and two grasshopper abdomens. The last three items were brought by the female who tried to feed them to the small young. The content of the sphinx caterpillar was eventually squeezed into the young's mouths, and one grasshopper abdomen was swallowed by the female itself after futile attempts to feed it to the young.

I did not observe wetlands similar to the one described above in the Wawa area (Michipicoten and Esquega townships, and the adjacent parts of Lake Superior Provincial Park) in 1999-2000 and no Le Conte's Sparrows were detected in other visited wetlands. However, this species likely occurs in low densities throughout Algoma District where suitable habitat is available.

Acknowledgments

I am grateful to Carol Dersch (Lake Superior Provincial Park) and Kim Taylor (North-Eastern Science and Technology, Ontario Ministry of Natural Resources) for help with plant identification, to George Peck (Royal Ontario Museum) who provided me with information on the number of confirmed nesting records of this species in Ontario, to Richard Knapton (University of Alberta, Edmonton), John C. Eitniear (San Antonio, Texas), A. J. Erskine and an anonymous reviewer for useful comments on this manuscript.

Conditions for Sexual Interactions Between Wild Grey Wolves, *Canis lupus*, and Coyotes, *Canis latrans*

Richard P. Thiel

Wisconsin Department of Natural Resources, Sandhill Wildlife Area, Box 156, Babcock, Wisconsin 54413 USA

Thiel, Richard P. 2006. Conditions for sexual interactions between wild Grey Wolves, *Canis lupus*, and Coyotes, *Canis latrans*. Canadian Field-Naturalist 120(1): 27–30.

Genetic evidence for the hybridization of wild Grey Wolves and Coyotes was first reported by Lehmann et al. (1991). Subsequent genetic and landscape-environmental analyses have attempted to grasp the extent of Wolf-Coyote crosses in North America. Since Wolves are normally territorial and thus aggressive towards Coyotes, hybridization events remain rare, not withstanding the taxonomic debates regarding *Canis* in eastern Ontario. In this paper I report on amicable interactions between Wolves and Coyotes observed in Wisconsin in recent decades and discuss circumstances that may lead to pairing between individuals of the two species.

Key Words: Grey Wolf, *Canis lupus*, Coyote, *Canis latrans*, interactions, hybridization, Wisconsin, Upper Great Lakes region.

Wolves and Coyotes can hybridize in captivity (Young and Goldman 1944; Silver and Silver 1969; Kolenosky 1971; Schmitz and Kolenosky 1985a, 1985b). Previously it was assumed that behavioral barriers prevented hybridization between *Canis* species (Wolf × Coyote) in the wild. Evidence of such crosses in the wild remained elusive until Lehman et al. (1991) reported on the presence of Coyote genes in Wolf mitochondrial DNA material from the Upper Great Lakes region of North America probably from crosses between female Coyotes and male Wolves. This stimulated further investigations (Roy et al. 1994; Pilgrim et al. 1998; Boyd et al. 2001; Wayne et al. 1995; among others), confirming the introgression of Coyote genes in Wolf mtDNA in a region extending from the western Great Lakes east to Quebec.

Confounding these findings, recent DNA studies among *Canis* in eastern Ontario and northeastern United States hypothesize the existence of a unique and putative Eastern (Timber) Wolf *(Canis lycaon* (Wilson et al. 2000, 2003) while other researchers argue the possibility that the Eastern Wolf is the Red Wolf (*Canis rufus*), or some type of a Wolf (*Canis lupus*) × Coyote hybrid (Schmitz and Kolenosky 1985a; Wayne et al. 1995; Nowak 2003; Wayne and Vila 2003; Phillips et al. 2003; Sears et al. 2003; among others).

It is speculated that the tumultuous ecological upheavals caused by Eurasian settlement of North America disrupted *Canis* communities creating conditions facilitating hybridization (Wayne et al. 1995; among others). Forest fragmentation and heavy exploitation of *Canis* populations are believed responsible for current hybridization between various *Canis* communities in southeastern Ontario (Sears et al. 2003; Theberge and Theberge 2004).

The question remains under what environmental – behavioral circumstances did (do) unions between Coyotes and Wolves occur, given the usual aggressive tendencies of Wolves to Coyotes? Lehman et al. (1991) believed that initial hybridization most likely occurred when young, male Wolves dispersed into an area with an endemic Coyote population where female Wolves were rare. I report encounters between Coyotes and Wolves in Wisconsin that support this theory during a period when Wolves were re-colonizing landscapes occupied by Coyotes. Because of the ongoing debate over *Canis* affinities in the east, I confine my comments to the Upper Great Lakes region of North America.

Methods

It is generally accepted that two taxonomically distinct wild canid species occur in Wisconsin: Grey Wolves *(Canis lupus)* and Coyotes *(Canis latrans)*. Natural re-colonization of Wolves in Wisconsin began in the mid 1970s from expansion of the Minnesota population (Mech and Nowak 1981; Thiel and Welch 1981). Wolf monitoring has been conducted since 1979 in Wisconsin involving techniques that include a combination of winter track surveys, aerial surveillance of radio-collared Wolves, summer howl surveys, and collection of reports by government employees and citizens (Wydeven et al. 1995). The following cases of Wolf-Coyote interactions are derived from visual observations from both ground and aerial surveillance, and from interpretation of trails in snow.

Results

Florence County

Trails, raise-leg urinations (RLUs) and radio telemetry data indicated that three lone male Wolves occupied home ranges near one another in western Florence County (45°50'N, 88°50'W) in northeastern Wisconsin between 1982 and 1984. At that time 17 – 25 Wolves lived in 2-4 packs along the Minnesota-Wisconsin border (46°15'N, 92°00'W), and in two north-central Wisconsin packs, 150 km southeast of the border

area (45°30'N, 90°00'W). The Florence County Wolves were 100 km east of the two north-central packs. One of these Wolves, male 077, was captured and collared, and aerially radio-monitored about once-weekly for 250 days between 6 May 1983 and 11 January 1984, occupying a 44 km^2 home range.

Several citizen and US Forest Service reports involved sightings of a Coyote trailing a lone Wolf in the areas occupied by the lone male Wolves. Wolf Project personnel also observed snow sign indicating that lone Wolves and Coyotes interacted. On 17 February 1982, Wolf Project technician, Larry Prenn, and I followed the trail of a Coyote and Wolf over 3 km. We were not able to ascertain the timing of each canid's travel, but based on highly convoluted trail maneuvers, it appeared they were traveling together. The Wolf was likely a male (RLUing) and the Coyote was a female (squat urinations, including one with blood).

On 6 December 1983, while homing in on the signal of Wolf 077 using a Cesna 180 fixed-wing aircraft, pilot Dan Doberstein and I saw a pair of canids lying within 15- 20 m on the ice of Halsey Lake. One appeared 2 or 3 times larger than the other. After determining that neither was Wolf 077, we began a slow descent. When approximately 200 m above them, the smaller canid stood up and quickly ran off into thick lowland conifer cover. We identified it as a Coyote. As it disappeared into cover, a third, larger canid ran from shore to where the second canid was still lying. On our third pass we approached within 10 m of these canids; the second one was larger, and we agreed they were both Wolves. Shortly thereafter we located Wolf 077 male 9.6 km to the east.

The following morning we attempted to inspect their trails, but high winds overnight and thin ice made interpretation challenging. We found outlines of two large tracks corresponding in size to Wolf, and one small Coyote-sized track. No evidence of a kill-site was found that might have attracted the two species.

Wood County

In each of seven winters between 1995 and 2002 high school students under my supervision followed the snow trails of a non-collared male Wolf, 501 that had escaped into the 36 km^2 Sandhill Wildlife Area (SWA) in Wood County (44°17'N, 90°10'W) (Thiel 2000; Thiel unpublished data) in May 1995. This is a deer research facility enclosed by 3 m tall × 29.5 km long fence. At that time, Wolves were colonizing this portion of west-central Wisconsin. In winter, 1996-1997, a territorial pair of Wolves colonized the area surrounding SWA. In January 1998, a pair of Wolves believed to be yearling siblings, entered SWA, and subsequent snowfall prevented them from digging out beneath the fence and leaving. Wolf 501 paired with one of these Wolves, a female based on bloody urine discovered on 20 January 1998. The third Wolf thereafter roamed the area as a loner.

In March a 6.5 year-old radioed Coyote was killed by Wolves within SWA. Likely, Wolf 501 male was involved in its death. Wolf 501 was last observed with another Wolf in October 1998. In four additional winters of snow tracking, Wolf 501 was the only Wolf detected within SWA.

On 22 January 2001, High School students reported trailing Wolf 501 male and encountered where the Wolf had physically interacted with a Coyote, resulting in an injury to the Wolf's right front foot. On 5 February several students and I encountered Wolf 501 male's trail where it intersected a Coyote's trail, heading in the same direction. In backtracking we determined the Coyote was a proestrus female based on bloody urine.

The mutual trail led to a 5 m × 5 m site completely padded down with Wolf and Coyote tracks. Numerous small droplets of blood and several tufts of canid fur were found in the padded-down site. Genetic testing to ascertain the species leaving the blood and fur was cost-prohibitive. By carefully back-trailing and following the tracks of both the Coyote and Wolf 501 male as they left the site we established the Wolf had been injured by the proestrus Coyote at the padded down site.

The Coyote and Wolf walked on the same trail for approximately 1 km beyond the padded down site before separating. Bloody Coyote urine was noted three times along this trail, and the Wolf inspected each. At one spot along the trail the Coyote and Wolf sat down within 1.5 m of each other. We followed the Wolf an additional 3.2 km after their trails separated. The Wolf RLU'd 8 times, and in each of five beds we found the imprint of his bloody limb.

It was evident that both canids were present together and spent considerable time at the padded down site. Since we found no evidence of prey remains, and since Wolf 501 male did not react aggressively when injured by the proestrus Coyote we concluded that his injury was caused by unwanted sexual advances.

At approximately 0830 (CDT) on 22 June 2001, amateur wildlife photographer, Rudi Van Stedum, saw male Wolf 501 male standing on rock talus in a forest in SWA at a distance of approximately 50 m. The Wolf was watching her as she idled her car along a woods trail. Simultaneously Van Stedum saw movement obliquely behind and left of the Wolf. A Coyote approached but retreated when it became aware of her car. Meanwhile, the Wolf turned and left the rock, facing her. At that point, the Coyote again approached the Wolf from behind and thrust its muzzle forcefully into the left rump of the Wolf. A yelp from the Wolf was clearly audible while the Wolf's gaze remained fixed on Van Stedum. The Coyote stepped back, and both stood still for a moment before the Wolf walked a ways off and turned momentarily to look at her. As the Wolf began slowly walking away, the Coyote approached it from behind and jabbed it a second time in its left hip with its muzzle. The Wolf yelped again. Both then trailed off into the undergrowth.

Wildlife biologist Wayne Hall and I inspected Van Stedum's photographs, and while they were taken in poor light conditions and no single frame showed both the Wolf and Coyote, the position of trees in the background of all photographs attested to the accuracy of her observation. Wolf 501 male roamed SWA alone in winter 2001-2002 and disappeared sometime after October 2002. No evidence of hybrids materialized subsequent to the observations in 2001.

Discussion

Coyote mtDNA in Wolves was calculated as the result of six hybridization episodes between male Wolves and female Coyotes (Lehman et al. 1991); Wayne and Vila (2003) speculated that, "... female wolves and male coyotes are more closely matched in size, and thus may also be more likely to mate...", but they further noted that no Coyotes sampled had Wolf-like haplotypes.

Several researchers have speculated that male Wolf dispersers provide the potential pool for male Wolf × female Coyote unions (Lehman et al. 1991; Wayne and Vila 2003; among others). While probably true, this is not necessarily because male Wolves disperse beyond the edge of Wolf range, as is implied. During winter 1983-1984, Michigan and Wisconsin DNR biologists discovered several lone male Wolves living in a several thousand square kilometer area. Some of these Wolves, like Wolf 077, seemed to have home ranges, as evidenced by RLU'ing (R. Thiel and J. Hammill, unpublished notes). They likely originated from at least 100 km away where the nearest known packs then existed. But female Wolves also dispersed to this area. In summer-fall 1986 radio-collared female Wolf 035 dispersed from Douglas County, Wisconsin (46°15'N, 92°00'W) 277 km to Iron County, Michigan (46°20'N, 88°59'W) and settled into a 174 km^2 home range, becoming the first known Wolf to reach upper Michigan since their demise in the late 1950s (Thiel 1988). The first breeding Wolf pack in upper Michigan would establish itself within this same area in 1990-1991 (J. Hammill, personal communication, 1 March 2004), implying that other female Wolves also dispersed to this region. The male Wolf × female Coyote hybridization hypothesis is therefore not explained in our region by any superior dispersal advantage displayed by male Wolves.

Because of their size, Wolves can easily overpower and kill Coyotes. Ballard et al. (2003: page 267, Table 10.4) summarized Wolf-Coyote interactions in Yellowstone National Park and noted that 11 percent of interactions resulted in killed Coyotes. In fatal encounters, the number of Wolves exceeded the number of Coyotes. Wisconsin biologists have also encountered aggressive interactions between Wolves and Coyotes, including killings of Coyotes. Killings involved superior numbers of Wolves (R. Thiel, unpublished data). In contrast, the few observations of single Wolf and Coyote encounters are not known to have resulted in killings. In the fall of 1981 pilot Jim Dienstl and I watched dispersing lone male Wolf 023 chase a Coyote from a White-tailed Deer (*Odocoileus virginianus*) fawn kill, but made no attempt to catch or kill it. SWA male Wolf 501 likely killed at least one Coyote when paired with a female Wolf. Four years later, this same male Wolf - who remained a loner in those four years - consorted with one or more Coyotes on at least three occasions; one case involving a proestrus female Coyote.

As in the Wisconsin cases reported here, Michigan DNR biologist, J. Hammill (personal communication, 1 March 2004), witnessed two separate incidents where a single Wolf and Coyote apparently traveled and bedded down together during the early years of Wolf recolonization.

Within Wolf range, owing to the aggressive stance pack Wolves normally display towards foreign Wolves and Coyotes (Arjo and Pletscher 1999; Ballard et al. 2003), hybridization events must be exceedingly rare. Observations reported here indicate that single Wolves are capable of genial behavioral interactions with Coyotes. Further, they suggest a potential for sexual advances of male Wolves towards female Coyotes, when and where male Wolves lack access to female Wolves. Unions between male Wolves and female Coyotes probably remain localized (however, note Schmitz and Kolenosky 1985a; Sears et al. 2003; and Theberge and Theberge 2004), and likely occur in areas of exceedingly low Wolf densities where access to female Coyotes by single male Wolves far exceeds access to female Wolves. Under such circumstances, hybridization is at least possible, and then depends on the behavioral nuances of these canids as individuals.

Acknowledgments

I thank L. D. Mech, United States Geological Survey, and A. Wydeven, Wisconsin DNR, for comments on an earlier draft of this manuscript.

Multiple Scale Den Site Selection by Swift Foxes, *Vulpes velox*, in Southeastern Colorado

Ann M. Kitchen[1], Eric M. Gese[2], and Sarah G. Lupis[1]

Kitchen, Ann M., Eric M. Gese, and Sarah G. Lupis. 2006. Multiple scale den site selection by Swift Foxes, *Vulpes velox*, in southeastern Colorado. Canadian Field Naturalist 120(1): 31–38.

Predation by Coyotes (*Canis latrans*) is a major source of mortality in Swift Fox (*Vulpes velox*) populations. Year-round den use by Swift Foxes is likely to be a predator avoidance strategy. Due to the importance of denning to Swift Fox ecology, we recorded den site selection of Swift Foxes in southeastern Colorado. Den site selection was recorded at two scales: microhabitat characteristics at the den and den placement within the home range. The number of den entrances, height and width of each entrance, aspect, hill position, slope, percent rock in soil, vegetative cover, and horizontal foliar density of 42 Swift Fox dens were examined during December 1999 – April 2000. This was compared to the same microhabitat characteristics at 42 random sites within Swift Fox home ranges to determine if Swift Foxes were using site characteristics according to their availability. Our results indicated that Swift Foxes were not highly selective of den sites based on the microhabitat characteristics evaluated in this study, although Swift Foxes selected areas of intermediate rock percentages. In addition, Swift Foxes were radio-tracked throughout the sample period and the location and frequency of use of known dens were recorded. Within the core area of home ranges, Swift Foxes used more dens (mean = 3.51 ± 1.70 (SD)), and had a higher frequency of use of dens (mean = 8.20 ± 6.01) than in the mid-range area (number of dens, mean = 0.90 ± 0.94; frequency, mean = 1.27 ± 2.12) and the boundary area (number of dens, mean = 0.34 ± 0.53; frequency, mean = 0.45 ± 0.93) of the home range. We discuss our results in terms of the importance of dens in facilitating escape from Coyotes. These results illustrate the need for examining den site selection at multiple scales to determine all selection factors, and to provide information useful for recovery and management efforts for this species.

Key Words: Swift Fox, *Vulpes velox*, denning, habitat selection, home range use, Colorado.

Introduction

The Swift Fox (*Vulpes velox*) is native to the short and mid-grass prairies of North America. The current range of the Swift Fox is much reduced from the historic range, and the species was formerly a candidate for endangered species listing (United States Fish and Wildlife Service 1996). The Swift Fox has been locally extirpated in the northern prairies in Canada, North Dakota, and much of South Dakota (Scott-Brown et al. 1987). One of the principal causes of Swift Fox population declines across much of the historical range is a reduction in suitable habitat (Hillman and Sharps 1978).

The combined availability and distribution of suitable den sites and escape holes is likely a habitat component for Swift Foxes (Egoscue 1979; Rongstad et al. 1989; Herrero et al. 1991). Swift Foxes were referred to as the "burrowing fox" by Lewis and Clark and are considered one of the most fossorial canids in North America because they use dens throughout the year (Kilgore 1969; Egoscue 1979). Swift Foxes spend the majority of diurnal hours in dens or near den entrances, often concurrently with a mate (Cutter 1958; Kitchen et al. 1999). Denning might enable Swift Foxes to maintain homeostasis by providing a cool, damp microhabitat refuge. Dens offer shelter from the elements and facilitate escape from predators, especially Coyotes (*Canis latrans*), in an environment that offers little natural cover (Egoscue 1979; Rongstad et al.1989; Herrero et al. 1991; Pruss 1999). Kitchen et al. (1999) found all Coyote-killed Swift Foxes near the periphery or outside their home range boundary, a significant distance from their nearest currently used den.

Thus, knowledge of habitat requirements for den sites might be an important component of Swift Fox conservation efforts (Hillman and Sharps 1978; Pruss 1999); however, results of studies on Swift Fox den site selection have varied. Swift Foxes may modify burrows dug by other animals such as American Badgers (*Taxidea taxus*), ground squirrels (*Spermophilus* spp.) or Black-tailed Prairie Dogs (*Cynomys ludovicianus*), or dig their own dens (Kilgore 1969; Hillman and Sharps 1978; Cameron 1984; Pruss 1999). Dens have been found in a variety of habitat types including short- and mid-grass prairie, grazed prairie, cultivated fields, fence rows, and rock outcrops (Cutter 1958; Hines 1980; Cameron 1984; Uresk and Sharps 1986; Rongstad et al. 1989; Pruss 1999). Occasionally, dens have been associated with man-made structures such as culverts, buildings, and cemetery gravesites with a concrete cap (Kilgore 1969; Hillman and Sharps 1978; Jackson and Choate 2000). Dens are frequently locat-

ed on or near tops of gently sloping hills, which are well drained and have a clear line of sight (Hillman and Sharps 1978; Cameron 1984; Uresk and Sharps 1986; Pruss 1999; Harrison 2003). However, dens also have been found in level, open areas and at the base of hills (Kilgore 1969; Hines 1980; Cameron 1984).

Den entrance characteristics vary among seasons and individual dens. There are indications that natal dens typically have more entrances than non-natal dens (Kilgore 1969; Hillman and Sharps 1978). Hines (1980) reported that Swift Foxes seem to select for entrances with west and east exposures. Similarly, Uresk and Sharps (1986) documented a trend toward dens with easterly exposures. In contrast, Rongstad et al. (1989) and Pruss (1999) found entrance exposure to be random.

An additional factor that might influence the selection of dens is the position of the site within the home range. Previous studies investigating den use in Swift Foxes have not considered den placement within the range as a factor influencing selection. We contend, however, that due to the importance of dens for predator escape (Herrero et al. 1991; Kitchen et al. 1999; Pruss 1999), placement relative to the home range core and boundary areas might be a driving force in selection. It is likely den placement is correlated to overall space use patterns and dens are positioned to facilitate a quick escape from an approaching predator.

The objective of this study was to determine the factors affecting den site selection for Swift Foxes on the Pinon Canyon Maneuver Site, in southeastern Colorado. We examined den site placement and microhabitat characteristics of active Swift Fox dens and compared these to sites not used by Swift Foxes.

Methods

Study Area

We conducted the study on the 1040-km^2 Pinon Canyon Maneuver Site (PCMS) in Las Animas County, Colorado. The dominant cover type on the PCMS is native grassland (60%), with Juniper (*Juniperus monosperma*) and Pinyon Pine (*Pinus edulis*) communities found in the hills and canyons (Shaw et al. 1989). Annual precipitation ranges from 26 to 38 cm (United States Department of Army 1980). Mean monthly temperatures range from –1°C in January to 23°C in July (Andersen and Rosenlund 1991). Predators known to kill Swift Fox are Coyotes (Covell 1992; Kitchen et al. 1999) and raptors (Covell and Rongstad 1990).

Swift Fox Capture

Swift Foxes were captured with double-door box traps (80 × 25 × 25 cm) baited with chicken or mackerel (Covell 1992). We deployed traps in the evening and checked them the following morning. Traps were not activated during periods when nighttime temperatures dropped below -10°C. We attached a radiocollar and ear tag to the Swift Fox and recorded the weight, sex and approximate age (using tooth wear) of the animal (Rongstad et al. 1989). All Swift Foxes were released at the site of capture. We followed telemetry procedures recommended by White and Garrott (1990). Locations were obtained by triangulating 2-3 bearings to the animal's position within a 10-minute period. Triangulation angles were maintained between 20° and 160° (Gese et al. 1988). We used aerial telemetry (Mech 1983) to locate missing animals. Telemetry error was determined by comparing telemetry locations with actual locations of stationary reference transmitters. When Swift Foxes were located in a den, we recorded the UTM coordinates of the den. We attempted to locate Swift Foxes approximately every 1-3 days with locations obtained throughout the 24-h period to reduce bias in home range estimates (used for den placement analysis).

Den Site Characteristics

Microhabitat characteristics of den sites were measured at a randomly selected sub-sample of the known active dens used by Swift Foxes during the breeding season (defined on the basis of energetic demands due to climatic changes and prey abundance, and behavioral characteristics to be 15 December to 14 April). Active dens were found by tracking radio-collared Swift Foxes. Den site selection was not stratified by sex as Swift Foxes form pair bonds with males and females concurrently using the same dens.

The following physical characteristics were measured at each den site: number of entrances, height and width of each entrance, den aspect, den position on hills, slope of site, percent rock in soil, vegetative cover, and horizontal foliar density. These characteristics were selected based on field observations and published descriptions of potentially important habitat characteristics (Hines 1980; Cameron 1984; Ursek and Sharps 1986; Rongstad et al. 1989; Covell 1992; Pruss 1999).

Den position on a hill was classified as bottom, middle, top, or flat when there was no hill. We determined maximum slope outside the den using a hand-held clinometer (Hays et al. 1981). The percentage of rock in the soil was visually estimated from the presence of rock in the dirt mound runway leading to the den entrance. Vegetation cover was determined by estimating the percent cover of grasses, forbs, shrubs, and bare soil in eight 1-m^2 plots randomly located within 10 m of the den. Percent soil and vegetation cover were estimated within the nearest 5% category. We indexed horizontal foliar density at 5 distances (10, 20, 30, 40, and 50 m) from the den in the four cardinal directions with a vegetation profile board and techniques for the fixed distance approach (Hays et al. 1981). The number of squares visible on a vertical board was counted by an observer lying down to approximate the visibility from the height of a Swift Fox.

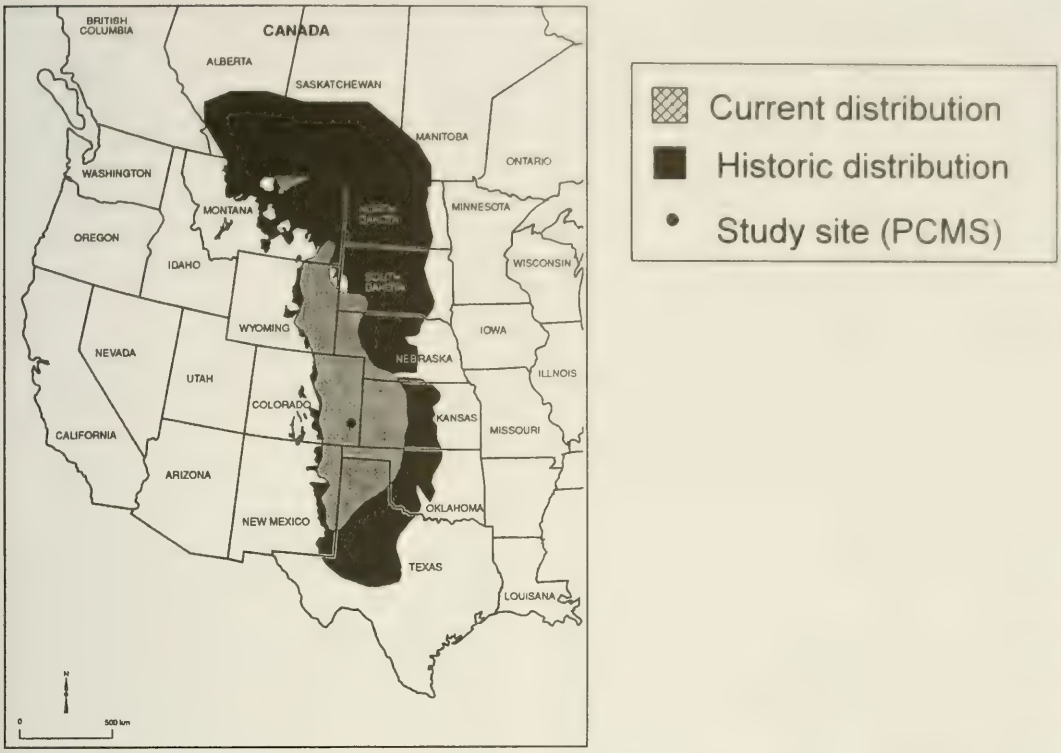

FIGURE 1. Swift Fox current and historic range and study area, Pinon Canyon Maneuver Site, Colorado, 2000.

Den Site Selection

To examine den site selection, we compared microhabitat characteristics of dens to control sites that represented available sites (Taylor et al. 1999). For each of the active den sites, we randomly selected one control site (not a den) within the Swift Foxes home range. We used the control site to compare the site characteristics of active den sites versus random sites within the Swift Foxes' home range. The control site was located 500 m away from the active den site in a random direction. This distance was arbitrary but allowed for selection of a random location within the home range. Because control sites were in the home range of the Swift Fox inhabiting the active den site, they were considered available as a possible denning location to the Swift Fox. The same den site characteristics were evaluated on the control sites, excluding variables associated with den entrances.

Den Placement

Dens used by Swift Foxes during the breeding season were recorded using telemetry procedures to assess the placement and use of the dens within the home range. The Swift Foxes' home ranges were described using a 95 % fixed kernel home-range estimator based on > 30 locations recorded within the breeding season (Worton 1989) with Arcview 3.0 software (Environmental Systems Research Institute, Inc., Redlands, California). Areas within the home range were then defined as the core area, which was the area within the 50% isopleth, the mid-range area, between the 50% and 75% isopleths, and the boundary area, between the 75% and the 95% isopleths. The number of dens and the frequency of use of those dens in the core, mid-range, and boundary areas of the home range were compared. In addition, we compared the number of dens in each area to the number expected from the proportion of each area in the home range; i.e., 50% within the core area, 25% within the mid-range area, and 20% within the boundary area.

Statistical Analysis

Because the habitat measurements were categorical, chi-square tests were used to assess the difference between habitat characteristics at active dens versus control sites (Zar 1999). Whether den entrances were randomly distributed around a circle (i.e., no predominant direction) was tested using Rayleigh's nonparametric Z test (Zar 1999). We attempted to predict class membership (i.e., active dens or control sites) by using a classification tree analysis with cost complexity pruning (CART: Verbyla 1987; S-Plus Version 6.0 1988-

2001.). Also called tree regression (Rejwan et al. 1999), this method repeatedly partitions the study sites into two groups (active dens and control sites) that are as similar as possible based upon the five variables common to both groups (position, slope, horizontal foliar density, percent rock in soil, and percent vegetative cover). Each of the independent variables is used at each step in the analysis regardless of whether they were previously used in the tree. The tree that is created is hierarchically structured with the complete data set at the top (the root) and the binary splits, referred to as "nodes", below to the final undivided "leaves" or groupings at the bottom of the tree. Analysis of variance with Tukey-adjusted post-hoc comparisons was used to assess the difference in the number of dens used and the number of times these dens were used by area (SAS Version 8.2 2001). Log transformations were used to achieve normality where deviations occurred. In cases where more than one den per Swift Fox was sampled, one den was randomly chosen for analysis to avoid pseudoreplication.

Results

Forty-two dens belonging to 42 Swift Foxes were located from December 1999 to April 2000 and used to evaluate den site characteristics. Most active dens had only one or two entrances and the maximum number of den entrances was seven. The mean height of den entrances was 19.4 ± 3.1 cm and the mean entrance width was 17.9 ± 2.5 cm. The percentage of dens with entrances oriented to the north, south, east, and west were 29.9, 21.1, 21.9, and 27.1%, respectively. These aspects were randomly distributed around a circle ($Z_{41} = 0.088$; $P = 0.54$), i.e., dens were not oriented in a predominant direction.

The mean maximum slope of active dens was 1.3 ± 1.3 degrees. We found no difference between the slope at den sites and control sites ($\chi^2 = 2.71$, df = 4, $P = 0.61$). Most dens (88.7%) and control sites (80.3%) were located on gentle slopes between 0 and 2 degrees. Four percent of control sites were located on slopes that exceeded 5 degrees, however, no dens were found on slopes that steep. The majority of Swift Fox dens were positioned either on flat ground or in the middle of a hill, and relatively few dens were located at the top or bottom of a hill (Figure 1). Control sites were found in similar positions with no detected difference between site position of used and control sites ($\chi^2 = 2.04$, df = 3, $P = 0.59$; Figure 1). We also found no difference in the pattern of visibility by distance from the den as compared to control sites ($\chi^2 = 0.06$, df = 4, $P = 0.99$). Visibility from both active den sites and control sites decreased uniformly in each direction as one moved away from the site. The vegetative cover of den sites and control dens was similar ($\chi^2 = 1.98$, df = 3, $P = 0.598$) with both dens and control sites occurring in areas mostly covered in grasses and soil (Figure 2). There was a significant difference in the percentage of rock at dens versus control sites ($\chi^2 = 8.91$, df = 3, $P = 0.03$; Figure 3) with dens having higher proportions of intermediate percentages of rock and control sites having higher proportions of rock below 5% or above 20%. The classification tree used to characterize the habitat at dens versus control sites failed to produce any biologically relevant pattern.

The average number of dens used per Swift Fox during the breeding season was 5.1 ± 2.1. The number of dens used by Swift Foxes varied by area of the home range ($F_{2,33} = 37.53$, $P < 0.001$; Figure 4a). Tukey's adjusted post-hoc tests indicated that more dens were used in the core area than in the mid-range and boundary areas (mid-range: $t_{33} = 6.29$, $P < 0.001$; boundary: $t_{33} = -7.54$, $P < 0.001$). There were also significantly more dens in the mid-range area than the boundary area ($t_{33} = -2.20$, $P = 0.035$). In addition, we found that the number of dens in each area varied from that expected from the proportion of the area, and thus the frequency of use of the area ($\chi^2 = 38.41$, df = 3, $P < 0.0001$).

Overall, there was a difference in the frequency of use of dens in the different areas of the home range ($F_{2,33} = 44.94$, $P < 0.001$; Figure 4b). The number of

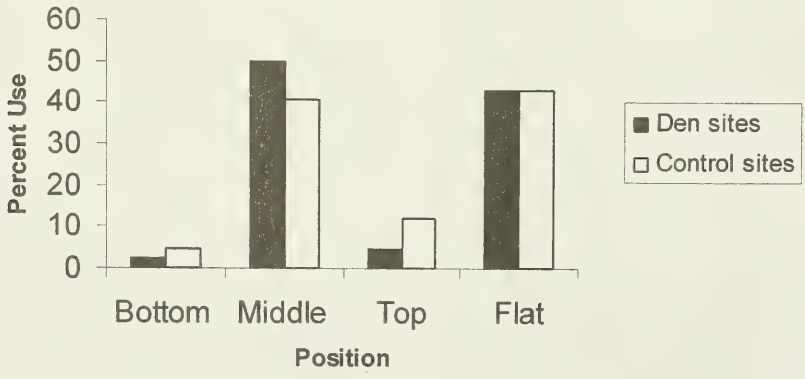

FIGURE 2. Position of Swift Fox den sites and control sites, Pinon Canyon Maneuver Site, Colorado, 2000.

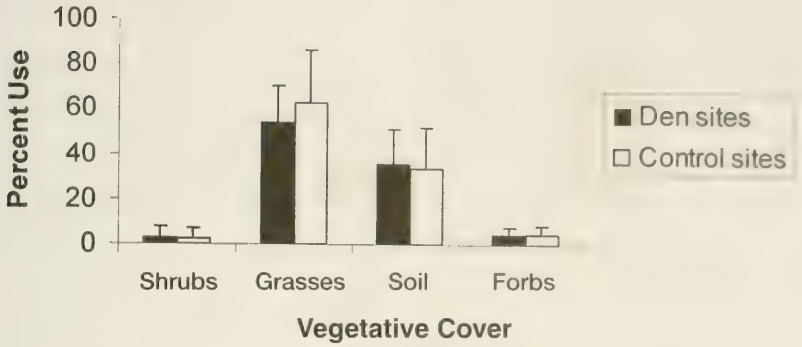

FIGURE 3. Vegetative cover at Swift Fox den sites and control sites, Pinon Canyon Maneuver Site, Colorado, 2000.

times that dens in the core area were used was higher than in the mid-range or boundary areas (mid-range: $t_{33} = 7.52, P < 0.001$; boundary: $t_{33} = 7.65, P < 0.001$). There was no difference in the number of times dens in the mid-range and boundary areas were used ($t_{33} = 1.55$, $P = 0.13$). The pattern of den use was variable. For example, one Swift Fox was located in only one den for a period spanning 67 days, while another Swift Fox used at least four different dens in a five-day period.

Discussion

Our results indicated Swift Foxes on the PCMS did not select den sites based on the microhabitat characteristics that we evaluated. However, Swift Foxes appeared to select areas of intermediate rock percentages. The selection of areas with intermediate rock percentages may be related to den structure and strength. Foxes had no preference for particular positions or vegetation at den sites despite other studies concluding that Swift Foxes preferentially selected den sites on hilltops (Uresk and Sharps 1986; Pruss 1999; Harrison 2003).

The finding that Swift Foxes in our study area select den sites with habitat characteristics that do not differ from control sites was not unexpected considering the homogeneous prairie environment on the PCMS. Our result does differ from other Swift Fox studies which reported preferences for certain habitat characteristics, however. The importance of selection of hill position and vegetation characteristics might be determined by variation in topography and habitat in the geographic area. Habitat selection by Swift Foxes on the PCMS appears to operate at the landscape level instead of at the den site level as Swift Foxes were only trapped on the open prairie on the PCMS despite efforts to capture Swift Foxes in wooded areas (Schauster et al. 2002).

Den site selection occurred at a larger scale; the placement of dens relative to areas within the home range was a significant factor in site selection. Foxes

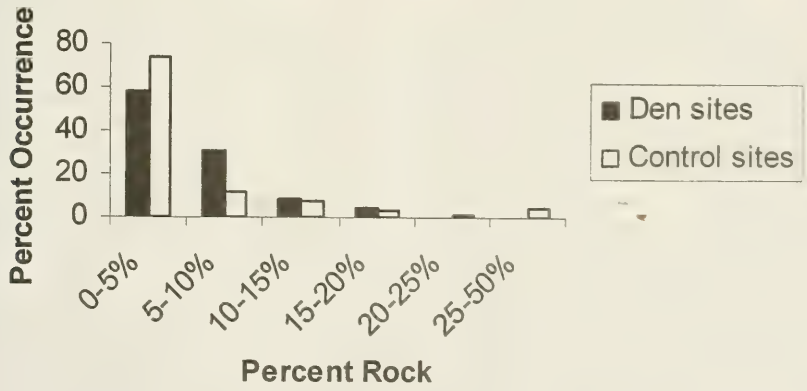

FIGURE 4. Percentage of rock at Swift Fox den sites and control sites, Pinon Canyon Maneuver Site, Colorado, 2000.

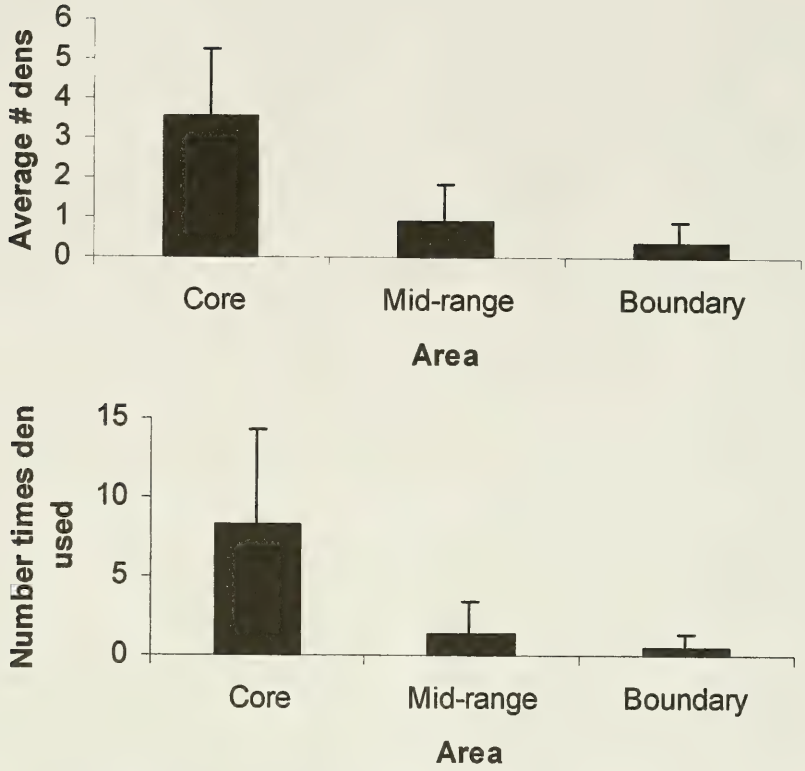

FIGURE 5. Placement of Swift Fox dens within the home range (top) and frequency of Swift Fox den use by area of the home range (bottom), Pinon Canyon Maneuver Site, Colorado, 2000.

used more dens in the core area of the home range as compared to the mid-range or boundary areas. In addition, dens in the core area were used more frequently by radio-tracked Swift Foxes than dens in the mid-range or boundary area. Den placement within the home range may be designed to facilitate escape from Coyotes. Previous studies have indicated that Swift Foxes use dens as a mechanism of escape from predators (Herrero et al. 1991; Kitchen et al. 1999; Pruss 1999) and that Coyote-caused mortality might be a key factor in limiting population growth in North America as well as the re-establishment of Swift Foxes on the Canadian prairies (Scott-Brown et al. 1987). Kitchen et al. (1999) found that all Coyote-caused Swift Fox mortalities occurred near or outside the Swift Fox's home range boundary, a substantial distance from their nearest currently used den.

Thus, Swift Foxes might maintain the majority of dens in the core area of the home range where they spend most of their diurnal hours (Schauster et al. 2002), and use dens only occasionally in the outer areas of their range to reduce encounters with and facilitate escape from predators. Previous studies have suggested that other preferences for den sites also might be due to Coyote avoidance, including den locations that are negatively associated with water sources (Pruss 1999), and dens that are closer to roads than unoccupied sites (Pruss 1994; Harrison 2003).

The importance of interspecific competition in determining den site selection has also been noted in Kit Foxes (List and Macdonald 2003) and Arctic Foxes (*Alopex lagopus*; Frafjord 2003). Frafjord (2003) documented that the distance to Red Fox (*Vulpes vulpes*) dens and the elevation from the tree line were the most important factors determining den use in Arctic Foxes. Kit Foxes in Mexico denned more often in grasslands and less in Prairie Dog (*Cynomys ludovicianus)* towns than expected (List and Macdonald 2003). These authors hypothesized that Kit Foxes reduced the amount of time they spent in Prairie Dog towns due to the activity of Coyotes.

Thus, Swift Fox den site selection in homogenous environments might be unrelated to microhabitat characteristics and more dependent on interspecific interactions and predator avoidance. This study also illustrates the importance of examining den site selection at multiple scales to determine all site selection factors. Due to the importance of denning to Swift Fox

ecology, a full understanding of den site selection in various environments is essential to recovery, reintroduction, and management efforts.

Jung, Thomas S., Brian G. Slough, David W. Nagorsen, Tanya A. Dewey, and Todd Powell. 2006. First record of the Northern Long-eared Bat, *Myotis septentrionalis*, in the Yukon Territory. Canadian Field-Naturalist 120(1): 39–42.

Three adult male Northern Long-eared Bats, *Myotis septentrionalis*, were captured in mist nets in July 2004 in the LaBiche River Valley, southeastern Yukon. These are the first records of *M. septentrionalis* in the Yukon. Further survey work is needed to delineate the extent of the range and population structure of this and other species of bats in northwestern North America.

Key Words: Northern Long-eared Bat, *Myotis septentrionalis*, distribution, Yukon.

The diversity and distribution of bats in northwestern North America (e.g., ≥55° N) is poorly documented. Few areas have been adequately surveyed, particularly for rare or cryptic species (*sensu* Nagorsen and Brigham 1993; van Zyll de Jong and Nagorsen 1994; Parker and Cook 1996; Parker et al. 1997). Youngman (1975) reported the Little Brown Bat (*Myotis lucifugus*) as the only species of bat in the Yukon. However, Youngman (1975) noted the possibility of other species occurring in the Yukon, such as the Big Brown Bat (*Eptesicus fuscus*) and Long-legged Bat (*Myotis volans*), based on single specimens collected near Fairbanks, Alaska, and Atlin, British Columbia, respectively. In the 30 years subsequent to Youngman (1975), no species of bats other than *M. lucifugus* have been confirmed from the Yukon. Slough (2000*), however, recorded a bat in southeastern Yukon that appeared to be a Big Brown Bat according to its echolocation call characteristics (C. Corben, personal communication), but it may have been a Silver-haired Bat (*Lasionycteris noctivagans*) and remains to be verified by a capture. We believe that species other than *M. lucifugus* may extend northward into the Yukon, and that a lack of records of other species is largely a function of previous search effort.

Based on a specimen collected in Nahanni National Park, Northwest Territories (van Zyll de Jong 1985), captures in recent surveys in adjacent British Columbia (Wilkinson et al. 1995*; Vonhof and Wilkinson 1997*), and an unidentified *Myotis* in a recording of an echolocation call (Slough 2000*), we suspected that the Northern Long-eared Bat (*Myotis septentrionalis*) and the Western Long-eared Bat (*Myotis evotis*) could be present in southeastern Yukon. In summer 2004, we undertook a preliminary field survey of the mammalian diversity in the boreal forest of southeastern Yukon, including a bat inventory. Here, we provide the first records of the Northern Long-eared Bat in the Yukon.

Methods

On 28 July – 2 August 2004, we used mist-nets to capture bats in the LaBiche River Valley (60.126°N, 124.064°W) of extreme southeastern Yukon. Mist-netting occurred at three sites; two sites were over small ponds (>150 m^2) within dense boreal forest, and another at an intersection of a roughly 3 m wide forest trail and a roughly 30 m wide forest access road. Nets were set across and bordering the ponds and perpendicular to the road and forest trail. Nets were opened 0.5 hr before sunset (about 23:00 hrs PDT) and closed 2–3 hr thereafter. A 6 m long mist net open for 1 hr was used as our definition of 1 mist-net hr.

Captured bats were examined for external diagnostic characteristics according to van Zyll de Jong (1985) and Nagorsen (2002), including presence of dark shoulder patches in the pelage, ear length, number of hairs on the trailing edge of the uropatagium, presence of keeled calcar, and relative length and shape of the tragus. We measured forearm length, ear length, and mass, and determined age as per van Zyll de Jong (1985). No voucher specimens were procured; rather, we obtained morphological measurements and wing punches for mitochondrial DNA sequencing to verify our field identifications. Wing punches were stored in 70% ethanol until lab analysis. Genetic analyses were conducted at the University of Michigan's Museum of Zoology (Ann Arbor, Michigan), and included an unweighted maximum parsimony analysis of 745 bp of the cytochrome *b* gene using 21 specimens of *Myotis* (Figure 1).

Results and Discussion

We amassed 42.1 mist-net hr over six nights of sampling; only six bats were captured. On 28 July 2004, we captured two adult male *M. septentrionalis* and one *M. lucifugus* at a small, shallow pond (ca. 108 m^2). On 29 July 2004, a third adult male northern *M. septentrionalis* and two *M. lucifugus* were captured at the same pond. Although three of our captures were consistent with the morphological traits of *M. septentrionalis* (Table 1), this species can be difficult to distinguish from other species of potentially sympatric long-eared *Myotis* (i.e., *M. evotis* and *M. keenii*), based on external characteristics alone (van Zyll de Jong 1979; Nagorsen 2002). DNA sequences, however, confirmed our tentative species identifications: the three *M. septentrionalis* are included in the *M. septentrionalis* clade (Figure 1).

The presence of *M. septentrionalis* in the Yukon is not surprising, considering that captures were reported from elsewhere in the Liard River Watershed by Wilkinson et al. (1995*), Bradbury et al. (1997*) and Vonhof and Wilkinson (1997*). The only voucher taken in those surveys to confirm identification, however, was a specimen of *M. septentrionalis* collected by Vonhof and Wilkinson (1997*) from the Fort Nelson River, British Columbia, near Highway 77 (Royal British Columbia Museum, RBCM 19516), about 140 km southeast of our captures. It is not known if there are breeding populations of *M. septentrionalis* in the Yukon, as no juveniles, or lactating or post-lactating females were captured. Breeding populations of the Northern Long-eared Bat, however, have been reported from nearby northeastern British Columbia (Wilkinson et al. 1995*, Vonhof and Wikinson 1997*). Similarly, it is not known if *M. septentrionalis* hibernates in the Yukon. No bat hibernacula have been found in the Yukon.

Despite low capture rates, we suspect that *M. septentrionalis* were locally common in our survey area, based on the number of captures relative to *M. lucifugus*. Moreover, we often detected what appeared to be *M. septentrionalis* at all of the mist-netting sites, based on low intensity echolocation calls (Faure et al. 1993) heard on narrowband bat detectors tuned to 40-50 kHz and observations of detection distances of passing bats. Our data, along with that of Wilkinson et al. (1995*), Bradbury et al. (1997*), and Vonhof and Wilkinson (1997*), suggest that *M. septentrionalis* may be locally common and widely distributed throughout the Liard River Watershed in British Columbia and the Yukon. We suspect that *M. septentrionalis* may occur throughout the Liard River Watershed in the Yukon, from the LaBiche River west to the Little Rancheria River. Other species of bats (e.g., *M. evotis*, *M. volans*, *Eptesicus fuscus*, and *Lasionycteris noctivagans*) may also be present in southern Yukon, but not yet confirmed with a capture, voucher, or DNA sample.

Perhaps the most intriguing question is whether *M. septentrionalis* is a long-established member of the Yukon mammalian fauna that has simply gone undetected, or, alternatively, is it a species that has recently (i.e. <100 years ago) colonized southeastern Yukon? Other mammals have recently colonized the Yukon, from the south, including: Mule Deer and White-tailed Deer (*Odocoileus hemionus* and *O. virginianus*; Hoefs 2001), Coyote (*Canis latrans*; Youngman 1975), and Cougar (*Puma concolor*; Jung et al. 2005). Moreover, Humphries et al. (2002) provided data from simulation models that suggested that the range of *M. lucifugus*, and presumably other species of bats in the boreal forest, would substantially move northward in response to global warming. Regardless of the origin of *M. septentrionalis* in the Yukon, these records underscore that our knowledge of the diversity and distribution, and population structure of bats in the Yukon is limited. Directed surveys are needed to address these information gaps and provide a basis for management and conservation initiatives that include bats.

Acknowledgments

S. Cannings and A. Runck kindly provided comments on an earlier draft of this note. Additional tissue samples for DNA sequence comparison were kindly provided by T. Dewey, P. Myers, D. Burles, and R. Benedict. The staff of Devon Canada Corporation's LaBiche River Gas Plant kindly went out of their way to accommodate us and provide logistical support. Funding was provided by the Yukon Department of Environment and NatureServe Yukon. Additional financial support was provided by a Northern Research Endowment Grant from the Northern Research Institute, Yukon College, to B. Slough.

TABLE 1. Age, sex, and morphometrics of *Myotis septentrionalis* ($n = 3$) captured in the LaBiche River valley, southeastern Yukon, 28-29 July 2004.

Specimen Label	GenBank Accession	Species[1]	Sex	Age	Forearm Length (mm)	Ear Length (mm)	Mass (g)
LaBiche-1	AY883902	*M. septentrionalis*	Male	Adult	16	37.7	7.6
LaBiche-3	AY883904	*M. septentrionalis*	Male	Adult	15	35.8	6.6
LaBiche-9	AY883905	*M. septentrionalis*	Male	Adult	14	37.6	6.9

[1] As tentatively identified in the field and subsequently confirmed with genetic analyses.

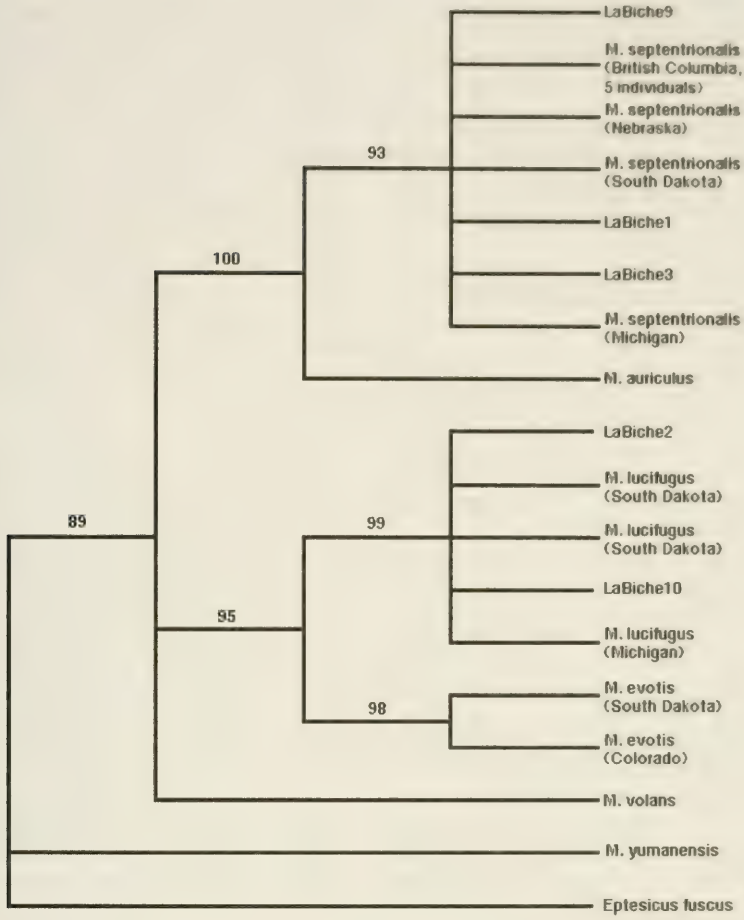

FIGURE 1. Placement of *Myotis septentrionalis* (LaBiche 1, 3, and 9) and *M. lucifugus* (LaBiche 2 and 10) samples collected in the LaBiche River Valley, Yukon, based on an unweighted maximum parsimony analysis of cytochrome *b* (745 bp) for these samples compared to other *Myotis*. *Eptesicus fuscus* is used as an outgroup. Numbers above the branches represent bootstrap support values for those nodes.

Recent Declines of House Sparrows, *Passer domesticus*, in Canada's Maritime Provinces

ANTHONY J. ERSKINE

16 Richardson Street, Sackville, New Brunswick E4L 4H6 Canada

Erskine, Anthony J. 2006. Recent declines of House Sparrows, *Passer domesticus*, in Canada's Maritime Provinces. Canadian Field-Naturalist 120(1): 43–49.

House Sparrows, *Passer domesticus*, were introduced to North America after 1850, increased and spread up to 1920, and stabilized or decreased thereafter until 1960. In the Maritimes (and perhaps some other areas), a further decline set in after 1970, continuing to the present. Now the species is rare to absent in much of the Maritimes, except around farms with livestock. Decline here since 1970 probably approaches 90 per cent in most other areas of human settlement except south of 45° N. Similar declines are known in the U.K., but seem poorly documented, if recognized, in North America outside of our region.

Key Words: House Sparrows, *Passer domesticus*, declines, New Brunswick, Nova Scotia, Prince Edward Island

Fifty years ago, House Sparrows (*Passer domesticus*; HoSp hereafter – a standard abbreviation used in many reports of organized birding activities) were so nearly ubiquitous in and around human settlements in eastern Canada that one sometimes had to "tune them out" to hear other birds. Then, it would have been unimaginable that this abundant species could become scarce in our lifetimes. HoSp, and their (urban) habitats, were virtually beneath notice both of birders and academics, so few serious studies of the species were made (see Kendeigh 1973), and none in Canada, during the rapid expansion of research on birds after World War 2. The result is a continuing scarcity of hard data on HoSp, precluding rigorous discussion of its population ecology. This study is a first look at what happened in the recent past and what may still be investigated usefully, in the Maritime Provinces of Canada [New Brunswick, Nova Scotia, and Prince Edward Island (hereafter "the Maritimes")].

HoSp were first introduced to North America around 1850, and became established in the Maritimes by the 1880s (Christie 1979; Lowther and Cink 1992). Numbers and densities in the next century are known mainly from anecdotal remarks in general accounts. As was general in eastern North America by the early 20th Century, HoSp were nearly ubiquitous and very common around human settlements, including cities, towns, villages, and even isolated farms. HoSp thrived on grain wastage, as well as using other food wastes. Nearly all human settlements, through the 1940s, harboured domestic animals, especially livestock and poultry, which were fed on small grains at least seasonally.

Motor vehicles began replacing horses in transportation by the 1920s, and the resulting decrease in horse droppings and other waste grain sources led to a decline in HoSp, documented mainly by general statements (e.g., Bent 1958). Motor vehicle use in the Maritimes was much less during the Great Depression of 1930s, when most people could not afford cars, and in World War 2, when gasoline and tires were reserved for military use. Use of horses again became widespread in those decades, and that presumably slowed or halted the earlier decline of HoSp. After the war, motor vehicles again became available, use of horses declined rapidly, and probably HoSp also declined. Very few bird counts were made in the Maritimes before 1960, when HoSp still were considered widespread and abundant (Squires 1952; Godfrey 1954; Tufts 1962). Winter bird counts at Wolfville, Nova Scotia (J. S. Erskine 1968) showed no obvious trend in HoSp numbers between 1948 and 1968. Christie (1979) summarized bird status changes in the Maritimes over the century to 1978, noting arrival, increase, and subsequent decline in HoSp, with numbers likely stable after 1930.

Starting in 1977, winter plot counts through 1988 in Sackville, New Brunswick (Erskine 1992b), showed further decreases in HoSp – evidently *not* related to decline of horses and other livestock, which already were absent in such towns (compare Erskine and McManus 2005). Also in the 1980s, Christie (1985 and following years) remarked on generally lower HoSp numbers on New Brunswick Christmas Bird Counts (CBCs hereafter). Some naturalists (personal communications) remarked on similar decreases in Nova Scotia in the early 1990s. The cooperative Breeding Bird Survey (BBS) documented HoSp declines across eastern Canada in summers 1967-1996 (Downes and Collins 2003), with decreases each decade (significant only in 1981-1990) in the Bird Conservation Region (BCR 14) including the Maritimes. HoSp continued to decline, and by 2000 were rare in Sackville, New Brunswick (personal observations), and in nearby towns.

In the near-absence of even quasi-systematic counts of HoSp, CBCs provided the only widespread sampling of bird numbers in the Maritimes, with many more counts in more years than the BBS. Although CBC data are poorly standardized (e.g., Dunn et al. 2005), those surveys are extensive enough, both here and across

Canada, to allow examination of HoSp occurrence in various habitats, in an attempt to identify factors involved in their recent declines.

Methods

Christmas Bird Counts are single-day annual counts in the period 13 December to 5 January, each restricted to a 24-km diameter circle selected subjectively. Bird species richness and availability of observers are usual selection criteria.

CBC data for HoSp in the Maritimes in 1960-2003 were extracted from *N. B. Naturalist* (formerly *Nature News*), *Nova Scotia Birds* (formerly *N. S. Bird Society Newsletter*), and *Island Naturalist*. Audubon publications (*American Birds*, formerly *Audubon Field Notes*) included many fewer counts ("circles" hereafter) in the Maritimes, and were used only to fill gaps in regional publication series. All data were tabulated in year vs. location matrices.

Data were selected by excluding circles surveyed in <=20 years and others with obvious "discontinuities" in coverage or effort. The selected circles were grouped by major non-urban habitat combinations, most including also some human settlements, thus (names in parentheses used in text and tables hereafter):

- (**Forest**) inland, predominantly forested, little or no farming;
- (**Coastal**) much forest or bog, farming insignificant;
- (**Farm=forest**) inland or coastal, farms and other open areas minor or unproductive but roughly equal in area to forests;
- (**Farm>forest**) farming major (much exceeding forest), relatively productive, usually around a sizable town;
- (**Major urban**) cities or larger towns, other habitats minor.

To allow for varying observer effort, between years or circles, published counts ("raw data") were also converted to birds/10 party-hours ("adjusted data"; see also Discussion).

Statistics on area changes in major habitats of the Maritimes over the study period (roughly 1960-2000) were assembled from Statscan websites, Canada Year Books, and some other directories.

Extrapolation from CBC data to Maritimes HoSp populations was attempted. Counts from the selected circles were expanded across the five habitat groupings above. Further adjustment was made to cover two important omissions in coverage:

- not all suitable areas within active CBCs were surveyed, and
- not all HoSp in the areas surveyed were detected.

Those factors could not be assessed rigorously, but "informed guesses" from personal experience (see Appendix) allowed tentative adjustment of extrapolated estimates.

Results

HoSp counts (adjusted data) for each selected circle in the various habitat-groupings were summarized as decade-means (1960-69, 1970-79, etc.; Table 1). Circles lacking data for >1 decade were excluded, as were those lacking 1 decade and >=3 years in a 2nd decade. Mean data were estimated for circles missing one decade, using ratios of HoSp counts in other circles in that and the next decade(s). Some general patterns were evident:

(i) a HoSp decline (from an earlier "plateau"), most often starting in the 1980s, was apparent nearly everywhere, in all habitats, and whether raw or adjusted data were compared;

(ii) the recent decline was less pronounced in circles where farmlands were important, or at least equal in area to forests, than elsewhere;

(iii) the recent decline began earlier in cities and large towns than elsewhere.

Observer effort in and around cities and towns in 1960-1979 increased so much that increased detection of HoSp then sometimes balanced or exceeded declines, which were less apparent in raw data vs. adjusted data.

Area changes in major habitats were substantial, as follows:

(a) Forests remained the largest land cover type in New Brunswick and Nova Scotia throughout; forest cover increased in Prince Edward Island, but that was minor in the overall picture. HoSp were never found in or near forests except in association with human settlements, so changes in forest area are ignored in further discussion.

(b) Among farmlands, "improved lands" (= crops, pasture, fallow; the main farmland types used by HoSp, aside from buildings) decreased in all provinces, by 35% in Prince Edward Island (where those remain dominant land-uses), and by 55% in New Brunswick and Nova Scotia, between 1961 and 1996. Published statistics available did not distinguish "commercial" and "marginal" farms; most decline in New Brunswick and Nova Scotia was in marginal farms, on which before 1960 farming was only one of several sources of income. Land-use on commercial farms became more intensive in 1961-1996 (personal observations), in the Maritimes as elsewhere, but that was not obvious from the published statistics.

(c) Urban area statistics allowed few generalizations. Larger communities mostly increased in human population and area, whereas many smaller ones decreased, some dwindling to scattered houses. Cultural changes within urban areas were many and widespread, involving sweeping changes in commerce, transportation, heating, garbage disposal, tolerance of livestock and poultry, recreation, etc. [see review in Erskine and McManus 2005]. Correlations with single factors in urban change could not be made rigorously so did not warrant statistical tests.

Table 1. Comparison of CBC HoSp means over decades, by habitats: (a) Raw data, (b) Adjusted data. Missing data added from ratios (of all groups) to next decade. Circles with no HoSp ever omitted.

(a) Raw data	1960-69	1970-79	1980-89	1990-99	2000-02
Forest areas					
7 circles	439	530	450	117	49
Coastal settlements, no farming					
11 circles	875	1306	1023	404	138
Farming & woodlands nearly equal					
11 circles	2120	2482	1823	949	735
Major farming areas, larger communities					
8 circles	3306	4596	4953	2695	1296
Cities					
4 circles	4017	3569	1664	374	157
Grand totals:	10757	12483	9913	4539	2375

(b) Adjusted data	1960-69	1970-79	1980-89	1990-99	2000-02
Forest areas					
7 circles	599	476	331	58	25
Coastal settlements, no farming					
11 circles	596	442	211	101	37
Farming & woodlands near equal					
11 circles	1255	927	672	216	160
Major farming areas, larger communities					
8 circles	2130	1840	1153	500	240
Cities					
4 circles	1568	1001	283	39	19
Grand totals:	6148	4686	2650	914	481

Extrapolated HoSp populations by decades, expanded from surveyed circles across suitable habitats, and adjusted for incomplete coverage and detection, are shown in Table 2.

That suggested that since the 1970s total HoSp numbers in the Maritimes decreased greatly, probably by three-quarters or more, with urban numbers – in New Brunswick and Prince Edward Island – diminishing to less than 10% of levels prevailing before 1980. Farmland HoSp numbers still may be one-half to two-thirds of those present 30-40 years earlier – more likely less. They now account for the vast majority of all HoSp remaining in New Brunswick, Prince Edward Island, and northern and eastern parts of Nova Scotia, where winter conditions and especially snow cover limit survival at that season. Numbers in western and southern Nova Scotia declined to a lesser degree.

Discussion

Johnston and Klitz (pages 15-52 *in* Pinowski and Kendeigh 1977) stated "The house sparrow seems clearly a product of interaction between sparrows and sedentary, agricultural man... This is a long-term relationship, sufficient to allow fine-grain adaptation of the birds to man's way." There seems no reason to dispute that generalization, on the long-term, broad-scale stage for which it was stated, but regional evidence suggested that "man's way" in the Maritimes recently changed more rapidly than did HoSp adaptations to it.

Generalization from CBC data. Rigorous conclusions regarding the recent HoSp decline in the Maritimes (or elsewhere) will not emerge from CBCs alone, but improved understanding may result when various kinds of information are combined. The scarcity of hard data on this species, anywhere in North America, is embarrassing. In the Maritimes and adjacent regions, the only multi-year study found that provided HoSp density indices directly was the one in Sackville, New Brunswick (Erskine 1992b) that stimulated this investigation. Knowledge of habitats and diet here relied on casual observations, as no planned studies had been made – and HoSp numbers in most areas now are too low for economical study.

CBC data are poorly standardized, and adjusting effort using party-hours addressed only a small part of variation in CBC data (compare Dunn et al. 2005). Regional data have not been examined rigorously, but it was obvious that the few – mostly urban – circles deploying large numbers of observers detected far fewer HoSp relative to effort than were found on most counts with fewer observers. Thus, declines in large urban areas may have been less drastic than indicated by the counts adjusted by party-hours, but they were impressive: compare means of raw data for 1966-1970 vs.

Table 2. Expansion of counts in Table 1 (raw data) to total Maritimes population estimates (explanation in Appendix).

Habitats	Extrapolated estimates				
	1960s	1970s	1980s	1990s	2000s
Forest+urban	1694	2045	1735	452	189
Coastal+urban	16944	25290	19809	7824	2673
(Farm=forest)+urban	55506	64980	47730	24846	19242
(Farm>forest)+urban	78520	109160	117630	64010	30780
Large urban	120510	107070	49920	11220	4710
farming	67013	87070	115752	71085	45020
urban	206161	221475	121072	37267	12574
Grand totals:	273174	308545	236824	108352	57594

1996-2000 at Fredericton (3379 vs. 53), Moncton (1046 vs. 142), Saint John (501 vs. 74).

Also, CBC data often were less adequate for HoSp than for most other bird species. When HoSp were abundant and ubiquitous in urban areas, some CBCs did not actually count them during the "census", merely inserting round-number estimates as reported totals. Where such obvious guesses recurred in several years, those counts were excluded. A more frequent problem was that parts of many urban areas, where HoSp were the most expectable birds, were ignored as unproductive (of more interesting species!) until HoSp decline was far advanced.

HoSp declines in urban areas. That the recent HoSp decline in the Maritimes began earlier in cities (except perhaps 'Greater Halifax') than less urbanized situations suggested that influences formerly encouraging HoSp to associate with human settlements are now less strong. Changes since 1960 in the regional urban milieu that might have been expected to affect HoSp numbers included:

Favourable influences

(i) winter bird-feeding increased greatly since 1960; however, small grains – preferred by HoSp (Bent 1958, also personal observations) – are now much less often presented (Rutherford 1984), feeding stations now offering mostly sunflower and thistle seeds, rather than oats, cracked corn, or "chicken scratch feed" mixtures;

(ii) shelter in urban hedges and other shrubs increased, presumably in response to increased disposable income of home-owners;

Negative influences

(a) food from human garbage, livestock wastage and manure decreased greatly, by disappearance of livestock, especially horses, and improved garbage disposal, these factors all related to increasing "urbanization";

(b) nesting and wintering shelter within buildings decreased, through removal of dilapidated structures and renovation of others – especially closing of openings (personal observations);

(c) transmittal of pathogens (e.g. *Salmonella*) may have been aided by increased transportation between urban areas (Erskine 1980b; a HoSp die-off at Charlottetown, Prince Edward Island, had been reported in the preceding winter);

(d) avian predators in towns (especially Merlin, *Falco columbarius,* and Sharp-shinned Hawk, *Accipiter striatus*) increased, with Merlins breeding in urban areas here since the 1980s; domestic cats, *Felis catus,* also increased.

The recent major decline of urban HoSp in the Maritimes indicated that urban areas no longer provide a favourable environment for this species, in winter or summer or both. Complete disappearance of HoSp in winter in many smaller human settlements suggested a "threshold effect"; below some population level, which likely varies with winter severity and availability of suitable habitats nearby, production in urban HoSp may no longer balance winter losses in this resident species.

HoSp declines in farmlands. HoSp decline in farming areas seemed better correlated with decreases in farms with livestock than with total numbers of farms or areas of "improved farmland". Loss of invertebrate food through pesticide use, as in England (D. Summers-Smith, letter), seems plausible but is unstudied here; chemical treatments in regional agriculture are obvious especially in potato- and fruit-producing areas, less so in grain production (mostly oats). Much Maritimes farmland area is inaccessible to HoSp in winter owing to snow cover. Livestock disappeared completely from most urban areas, and also from many former farms now used as rural residences or "hobby farms". Horses are scarce generally, and cattle now are mostly found in large feed-lot operations, where larger birds (gulls, pigeons, corvids, starlings) often out-compete HoSp – though a few of the latter persist (personal observations). Concentrations of HoSp persist in productive farming areas, even when disappearing from nearby towns, presumably because livestock operations now are mainly in better farming areas.

From the viewpoint of agriculture (and general economy), the Maritimes are a "backwater". Agriculture here ranks far behind forestry, tourism, fisheries, and "gen-

eral service" on economic and employment indices, despite the local importance of potatoes and orchards. Snow cover and related temperatures are major factors limiting agriculture (and HoSp) here. Soils and geology underlie the picture, with limestone areas very limited. Agricultural changes since World War II involved abandonment of former marginal agricultural lands rather than intensified use of better farmlands.

HoSp responses to habitat changes. All CBC habitat groupings used herein involved combinations of human settlements, of varying size, with nearby habitats, among which only farmlands were regularly used by HoSp. Human settlements formerly provided HoSp with both sheltered nesting places and nearby feeding opportunities. After nesting, urban HoSp often withdrew from built-up areas to glean waste grain in agricultural lands within a radius of 2-3 km, returning to towns and villages with the approach of winter (personal observations; Summers-Smith 1963). Where little farmland exists near urban settlements, in forested regions (e.g., Miramichi, New Brunswick) or within larger cities, urban HoSp presumably depended year-round on feeding opportunities within the city.

Cultural changes altered urban areas more, as well as in different ways, than farmlands. Thus, HoSp in areas that combined extensive farming with urban settlements were (and are) less restricted for feeding than those relying year-round on urban areas. Recent trends suggest that HoSp might disappear within a few decades from most urban habitats in New Brunswick and Prince Edward Island, where snow-cover limits their use of non-urban habitats in winter. They may persist longer in "Greater Halifax", and in some towns in farming areas of western Nova Scotia, where snow cover is less and winter temperatures more moderate. Such changes presuppose continuation of climates similar to recent decades; if "global warming" brings markedly less snow here, numbers of a winter-limited species – as HoSp appears to be – might again increase.

Estimating HoSp populations. Extrapolating observed numbers across potential HoSp habitat to regional populations (Table 2) involved much "informed guesswork", as hard data do not exist for most needed adjustments. Valuable perspective may emerge from such simple "modeling", even though it lacks rigour and precision.

Modeling allowed comparison with the only other independent estimate of Maritimes HoSp populations, derived from abundance indices in the Maritimes breeding bird atlas (Erskine 1992a) in 1986-1990. The Atlas estimates used a general algorithm (C. Field and P. Payzant, Appendix D *in* Erskine 1992a) for extrapolation to areas unsampled or lacking abundance indices; that algorithm may not have been fully appropriate for HoSp, of which density varied greatly between habitats. The Atlas estimate of HoSp (140 000 pairs) was of a similar order to that for the same period (1980s) in Table 2 (ca. 240 000 individuals).

The HoSp situation elsewhere. No systematic studies of HoSp were available in other parts of Canada. CBC data there – tabulated and adjusted for party-hours as in the Maritimes (unpublished MSS) – revealed no such drastic HoSp declines as seen here in 1960-2003.

Continuing availability of small grains in both rural and urban areas of the Prairie Provinces south of the boreal forest were well-correlated with the highest HoSp CBC counts on the continent, with no suggestion of declines unrelated to count efforts. British Columbia CBC data were extremely variable, with generally low numbers, as was to be expected from the varied geography and relative scarcity of arable farming. No long-run counts suggested continuing declines in HoSp there. Very few long-run counts were available in northern, deep-snow areas of western Canada, where most showed no HoSp at any time.

Quebec experiences the largest average snowfalls in Canada outside the western mountains. Most of the few long-run (>20 years) CBCs in Quebec suggested some decline in recent decades, from "adjusted counts", as reported also from independent surveys (1970-1991) by Cyr et Larivée (1995); those declines were less extreme than in the Maritimes.

In Ontario, where CBCs are more numerous than elsewhere in Canada, HoSp (raw) numbers remained generally stable over the decades, except in a few long-run urban circles near the northern limits of human settlement. Adjusted data, however, suggested declines, starting in 1980s, on nearly half the long-run counts; Sudbury showed the largest proportional decline, and counts at Sault Ste. Marie and Thunder Bay, also northern areas with much snow cover — and despite both being ports involved in grain shipping from the Prairies, also declined.

In the United Kingdom, where the HoSp situation has been followed for decades, especially by Denis Summers-Smith (1963, 2003, and letters), declines evidently are of a similar order to those found in the Maritimes. Although research on HoSp is limited there too, much detailed information is available on habitat relations of HoSp in the U.K. Summers-Smith's conclusions (op. cit.) regarding causation agree well with tentative inferences suggested here for the Maritimes – despite the near-absence of snow cover as a limiting factor in the U.K. The intensity of agriculture there is much more comparable to that in southern Ontario or the Prairie Provinces than to the Maritimes. At this time it seems likely that many different factors, some general and widespread, others applying only regionally, are involved in recent declines of HoSp in the wider picture.

A recent discussion of HoSp decline in North America (Holder 2003) drew on wide-ranging surveys, including BBS and CBC, but reached few con-

clusions except that competition with recent House Finch populations had not affected HoSp numbers. Use by Holder of only CBCs reported to Audubon limited his understanding of the Maritimes situation. His expressed suggestion (page 65) that the HoSp situation in Canada might parallel that in the U.K. – where very different climatic and economic regimes prevail – seems unlikely.

Acknowledgments

Thanks to the many observers and compilers of CBCs whose data were used in this study, and also to publishers and editors of magazines (named in text) in which those reports were presented. Denis Summers-Smith (U.K.) and Jenny De Laet (Belgium) commented very helpfully on an earlier version of the MS. Reviewers for this journal provided much-needed encouragement as well as helpful suggestions for improvement of the text.

Appendix

(i) Factors, by habitat groupings, for expansion from long-run CBC circles to total areas in Maritimes. Note: Forest areas support very few or no HoSp, so those areas were ignored, except where CBCs had been done.

Habitats	Number long-run CBC circles		Potential CBC circles + other potential habitat
Forest + urban	7	add	8
Coastal + urban	11	add	60
(Farm = forest) + urban	11	add	37
(Farm > forest) + urban	8	add	11
Large urban	4	add	4

(ii) Expansion factors, by habitat groupings, for incomplete coverage of suitable habitats in circles and incomplete detection of HoSp in areas covered.

Habitats	Coverage	Detection
Forest + urban	1.2	1.5
Coastal + urban	2.0	1.5
(Farm = forest) + urban	3.0	2.0
(Farm > forest) + urban	5.0	2.0
Large urban	5.0	3.0

(iii) Segregation of HoSp numbers among habitats, where appropriate. Forest and coastal habitats omitted as not used by HoSp; thus only 3rd & 4th categories above required segregation, with proportions varying over time.

Decades	1960s	1970s	1980s	1990s	2000s
Farm:urban ratio	50:50	50:50	70:30	80:20	90:10

First Record of the Southern Red-Backed Vole, *Clethrionomys gapperi*, in Newfoundland: Implications for the Endangered Newfoundland Marten, *Martes americana atrata*

Hearn, Brian J., John T. Neville, William J. Curran, and Dean P. Snow. 2006. First record of the Southern Red-Backed Vole, *Clethrionomys gapperi*, in Newfoundland: implications for the endangered Newfoundland Marten, *Martes americana atrata*. Canadian Field Naturalist 120(1): 50–56.

We report on the first capture of the Southern Red-backed Vole (*Clethrionomys gapperi)*, the eleventh non-native terrestrial mammal established on the island of Newfoundland over the last 150 years. Red-backed Voles may have been accidentally introduced by unknown sources in pulpwood imports or may have been deliberately introduced in an attempt to augment the depauperate small mammal fauna as a vigilante recovery effort for the endangered Newfoundland Marten (*Martes americana atrata)*. We anticipate significant utilization of the Red-backed Vole as prey by both Newfoundland Marten and Red Fox (*Vulpes vulpes*) with associated demographic responses within and between these species. Red-backed Voles will likely change habitat utilization patterns for the endemic subspecies of Meadow Vole, *Microtus pennsylvanicus terraenovae*.

Key Words: Southern Red-backed Vole, *Clethrionomys gapperi*, Marten, *Martes americana atra*, introduced species, Newfoundland.

The island of Newfoundland has only 13 resident native species of terrestrial mammals (Bangs 1913; Cameron 1958; Dodds 1983; Table 1). A fourteenth species, the Newfoundland Wolf (*Canis lupus beothucus*) was extinct by the early 20th century (Allen and Barbour 1937), and one of the three native mustelids, the Newfoundland Marten (*Martes americana atrata*) is currently listed by the Committee on the Status of Endangered Wildlife in Canada as endangered (Lemon 1996*). As well, the indigenous community of terrestrial mammals in Newfoundland has a skewed composition, with a disproportionate number of predators and few prey species; historically, only one microtine, the native subspecies of Meadow Vole (*Microtus pennsylvanicus terraenovae)* occurred on the island (Dodds 1983). Moreover, Cameron (1958) considered 10 of the 14 native species of terrestrial mammals as endemic subspecies; recent genetic analysis has confirmed the subspecies classification of the Newfoundland Marten (Kyle and Strobeck 2003). However, over the last 150 years, an additional nine species of mammals have been either intentionally or accidentally introduced to the island (Dodds 1983; Gould and Pruitt 1969; Northcott 1974*; Northcott et al. 1974; Payne 1976; Table 1). A tenth species, the Eastern Coyote (*Canis latrans*) became established on the island of Newfoundland in 1985, likely after crossing on sea ice from mainland Nova Scotia (Parker 1995). Herein, we report the first record of the eleventh non-native mammal established on the island of Newfoundland, the Southern Red-backed Vole (*Clethrionomys gapperi),* and discuss the circumstances and implications of this recent introduction, particularly with reference to the Newfoundland Marten.

Field Sites and Sampling

Between 2 and 5 November 1999, as part of a larger study investigating the demography and ecology of the Newfoundland Marten, we indexed small mammal populations on four sites inside the Pine Marten Study Area (PMSA) in southwestern Newfoundland (48°37'N, 57°53'W). The PMSA is a 2078-km^2 wildlife reserve, that was created in 1973 by the Newfoundland and Labrador Wildlife Division, for the protection of the Newfoundland Marten (Snyder and Bissonette 1987). Sites 1–3 were overmature (81+ years), Balsam Fir (*Abies balsamea)* stands, whereas Site 4 was a regenerating (10–15 yrs) Balsam Fir stand that regenerated after an outbreak of Spruce Budworm (*Choristoneura fumiferana*) and Hemlock Looper (*Lambdina fiscellaria fiscellaria*) in 1987. Site 4 contained a mix of young Balsam Fir and early successional species, such as White Birch (*Betula papyrifera*) and Pin Cherry (*Prunus pensylvanica*), had a significant number of dead Balsam Fir snags, and had no canopy. Each site was trapped with 100 snap traps on 3 consecutive nights. Traps were baited with peanut butter, and placed in pairs at 50 trapping stations, spaced 15 m apart, yielding a 735-m transect, following the methods previously used by Thompson and Curran (1995). All captures were recorded and collected for further analysis.

Forty small mammals were collected on the four sites over 1200 trap nights: 8 Meadow Voles, three Deer Mice (*Peromyscus maniculatus*), 10 Masked Shrews (*Sorex cinereus*), and 19 Southern Red-backed Voles. How-

TABLE 1. Native and non-native[1] terrestrial mammals on the island of Newfoundland prior to the discovery of the Southern Red-backed Vole[1].

Order	Family	Scientific Name (Authority)	Common Name
Insectivora	Soricidae	*Sorex cinereus acadicus* (Gilpin)	Masked Shrew *
Chiroptera	Vespertilionidae	*Myotis lucifugus lucifugus* (Le Conte)	Little Brown Bat
		Myotis septentrionalis (van Zyll de Jong)	Northern Long-eared Bat
Lagomorpha	Leporidae	*Lepus arcticus bangsii* (Rhoads)	Arctic Hare
		Lepus americanus struthopus (Bangs)	Snowshoe Hare *
Rodentia	Cricetidae	*Microtus pennsylvanicus terraenovae* (Bangs)	Meadow Vole
		Peromyscus maniculatus (Wagner)	Deer Mouse *
		Ondatra zibethicus obscurus (Bangs)	Muskrat
	Scuridae	*Tamiasciurus hudsonicus ungavensis* (Anderson)	Red Squirrel *
		Tamias striatus lysteri (Richardson)	Eastern Chipmunk *
	Castoridae	*Castor canadensis caecator* (Bangs)	Beaver
	Muridae	*Rattus norvegicus norvegicus* (Berkenhout)	Norway Rat *
		Mus musculus domesticus (Rutty)	House Mouse *
Carnivora	Mustelidae	*Mustela erminea richardsonii* (Bonaparte)	Short-tailed Weasel
		Mustela vison (Schreber)	Mink *
		Martes americana atrata (Bangs)	Newfoundland Marten[2]
		Lontra canadensis degener (Bangs)	Otter
	Felidae	*Lynx lynx susolanus* (Bangs)	Canada Lynx
	Canidae	*Vulpes vulpes deletrix* (Bangs)	Red Fox
		Canis lupus beothucus[3] (Allen and Barbour)	Eastern Timber Wolf
		Canis latrans var. (Lawrence and Bossert)	Eastern Coyote *
	Ursidae	*Ursus americanus hamiltoni* (Cameron)	American Black Bear
Arctiodactyla	Cervidae	*Rangifer tarandus terraenovae* (Gmelin)	Woodland Caribou
		Alces alces americana (Clinton)	Moose*

[1]Several other species are either seasonal visitors (e.g., Arctic Fox (*Alopex lagopus*), Polar Bears (*Ursus maritimus*)) or have been introduced to offshore islands (e.g., Bison (*Bison bison*), Bank Vole (*Clethrionomys glareolus suecicus*)). Adapted from Cameron (1958) and Dodds (1983).
[2]Subspecies designation confirmed via recent genetic analysis (Kyle and Strobeck 2003).
[3]Extinct

ever, Red-backed Voles were captured on only two of the four sites (Sites 3 and 4). The two sites where Red-backed Voles were captured were approximately 6 km apart, but on opposite sides of Little Grand Lake. Movement between these two sites would require an overland dispersal of at least 11 km, suggesting that the species is well established in the area. At least one of the collected females had obvious placental implantation scars on the uterine horns, indicating recent breeding. Species identification was confirmed by pelage and dental characteristics (Banfield 1974).

Discussion

Sites 1–3 had previously been snap trapped for small mammals for 4 years, between 1990 and 1993 (Thompson and Curran 1995). Additionally, Site 4, as well as the general area encompassing all four of our sampled sites, was extensively live trapped from 1993 to 1997, as part of a larger study investigating Marten, small mammal communities, and forest structure (Adair 2003). Neither of these two previous trapping efforts captured Red-backed Voles, suggesting that the species had recently become established, most likely sometime during or after 1998. Moreover, a more extensive small mammal survey, conducted two weeks before this survey in the Red Indian Lake area, approximately 35 km east of our four trapping sites, using identical methods but involving 16 sites and >4900 trap-nights, captured 116 small mammals, but no Red-backed Voles. Autumn (October) small-mammal surveys in the Red Indian Lake area, repeated annually since 1999, have subsequently documented the arrival (2001) and eastward dispersal of the Red-backed Vole in southwestern and south-central Newfoundland (B. J. Hearn, unpublished data).

Two explanations for this introduction are possible. Red-backed Voles may have been accidentally introduced in pulpwood or pulp chips imported through the port of Stephenville, (approximately 38 km SW of our sampling sites). Alternatively, the species may have been deliberately introduced by unknown persons to increase prey diversity and abundance for the Newfoundland Marten. Because Red-backed Voles are a common prey item in the diet of American Marten elsewhere (Martin 1994), this management option was debated during preparation of the Newfoundland Marten Recovery Plan (Forsey et al. 1995*), resulting in a divergence of opinions among local stakeholder groups. Although ultimately rejected by the Newfoundland Marten Recovery Team as an ethical recovery action, the limited prey base and the ecological consequences of introducing the Red-backed Vole were publicly discussed in 1998, during a two-day symposium on issues concern-

ing the Newfoundland Marten. Given the coincidence in timing (ca. 1998) and spatial distribution of this discovery (inside the PMSA), we suggest that it is likely that Red-backed Voles were deliberately introduced.

Regardless of the source of this introduction, the direct and indirect effects of this new species on community structure in general, and the Newfoundland Marten in particular, warrant investigation. As an example, Cameron (1958) reported that Newfoundland Meadow Voles are less selective in their habitat requirements than mainland Meadow Voles, and atypically, occupy forested habitats — likely due to the historical absence of Red-backed Voles (Cameron 1958; Clough 1964; Cameron 1965; Morris 1969; Folinsbee et al. 1973). Consequently, the introduction of the Red-backed Vole will probably result in a niche contraction for the endemic Meadow Vole, and we predict that Meadow Voles will be displaced from forested areas and restricted to their preferred habitat (i.e., moist meadow-like areas (Folinsbee et al. 1973)). Preliminary analysis of our 1999–2006 small-mammal trapping data from the RIL area is documenting an irrupting population of Red-backed Voles (>3000 Red-backed Voles captured since 2001), and an essential elimination of Meadow Voles from forested sites where we had previously captured Meadow Voles.

Consequently, the positive effect of increased prey diversity and biomass for the Newfoundland Marten will be offset, to some degree, by a decrease in distribution and densities of Meadow Voles, which have been a historically important prey species (Bateman 1986; Drew 1995; Gosse and Hearn 2005; Tucker 1988). Further, indirect effects of the Red-backed Vole on Newfoundland Marten could occur as a result of the impact of this species on local Red Fox (*Vulpes vulpes*) populations. Given the depauperate prey base in Newfoundland, Red Fox and Marten display considerable dietary overlap, and Red Fox are the most important natural predator of Newfoundland Marten (B. J. Hearn, unpublished data). Consequently, Marten may be negatively affected if the introduction of Red-backed Voles has a positive effect on Red Fox demography, leading to increased intraguild predation on Marten (Lindström et al. 1995) or increased Marten–Fox competition for food (Kurki et al. 1997; Lindström et al. 1994; Marcström et al. 1988). Pine Marten (*Martes martes*) populations in Scandinavia increased in the 1980s, following a decline of Red Fox due to a sarcoptic mange epidemic, as a direct result (hypothesized) of reduced predation by Red Fox (Lindström et al. 1994; Helldin 1998) or reduced competition for *Microtus* prey (Storch et al. 1990). Although counterintuitive to conventional competition theory, increases in food resources (prey availability) can actually increase intraguild predation by supporting increased populations of the superior competitor. Parallel circumstances have been described for other threatened or endangered carnivores elsewhere (e.g., Coyote predation on Swift Foxes (*Vulpes macrotis*) (Sovada et al. 1998), Coyote predation on San Joaquin Kit Foxes (*Vulpes macrotis*) (Ralls and White 1995; White and Garrott 1997; Cypher and Spencer 1998), and Lion (*Panthera leo*) and Spotted Hyena (*Crocuta croenta*) predation on African Wild Dogs (*Lycaon pictus*) (Creel 2001; Creel et al. 2001)). African Wild Dog densities are actually lowest where density of their major prey is highest, due to intraspecific predation (Mills and Gorman 1997). It is noteworthy that Marten live-trapping captures on the Northern Peninsula of Newfoundland increased in 2005 following a recent (2002-2004) rabies outbreak (Whitney 2004*) that virtually eliminated Red Fox from the local landscape (M. McGrath, personal communication).

Changes in prey availability clearly affect densities of carnivores, improving demographic performance (i.e., increased reproductive output and survival (Fuller and Sievert 2001). Furthermore, decreased food resources have been associated with reduced population density or trapper success, enlarged home ranges, and lower reproductive performance of American Marten (Bulmer 1974; Fryxell et al. 1999; Poole and Graf 1986; Simon et al. 1999; Thompson and Colgan 1987). The reduced prey base for Marten in Newfoundland compared with that available on the mainland portion of the province (Labrador) has been suggested as a likely explanation for the difference in the demographic health of these two populations (Bissonette et al. 1988*). By comparison, Labrador has 17 small mammal species, including the Red-backed Vole (Tucker 1988) and Marten populations appear capable of supporting a commercial harvest; 500-800 Marten were harvested annually between 1995 and 1998 (Simon et al. 1999).

However, an increase in vole biomass may not lead to an immediate increase in Marten densities if territory size in Newfoundland is adjusted to the lowest (or historical) level of prey availability. Such appears to be the case for European Badger (*Meles meles*) in Scotland (Kruuk and Parrish 1982), Kit Foxes in California (White and Ralls 1993), and some Coyote populations in the western United States (Mills and Knowlton 1991). Interestingly, Payer (1999) in the largest American Marten study reported to date ($n > 140$ marten ranges), found no difference in mean home-range area for American Marten in Maine between 1995-1998, despite a three-fold decline and recovery in small mammal populations. Thompson and Colgan (1987, 1990) suggested that, based on energetics, Marten in Ontario cannot survive exclusively on small rodents during late winter, and further, take small mammals opportunistically as they hunt for larger prey (i.e., Snowshoe Hare). Moreover, Gosse and Hearn (2005) reported that Snowshoe Hare provide >90% of the caloric intake of Newfoundland Marten in winter, the most energetically stressful period annually (Buskirk et al. 1988). As cautioned by Fuller and Sievert (2001), the correlation between food and density-related demo-

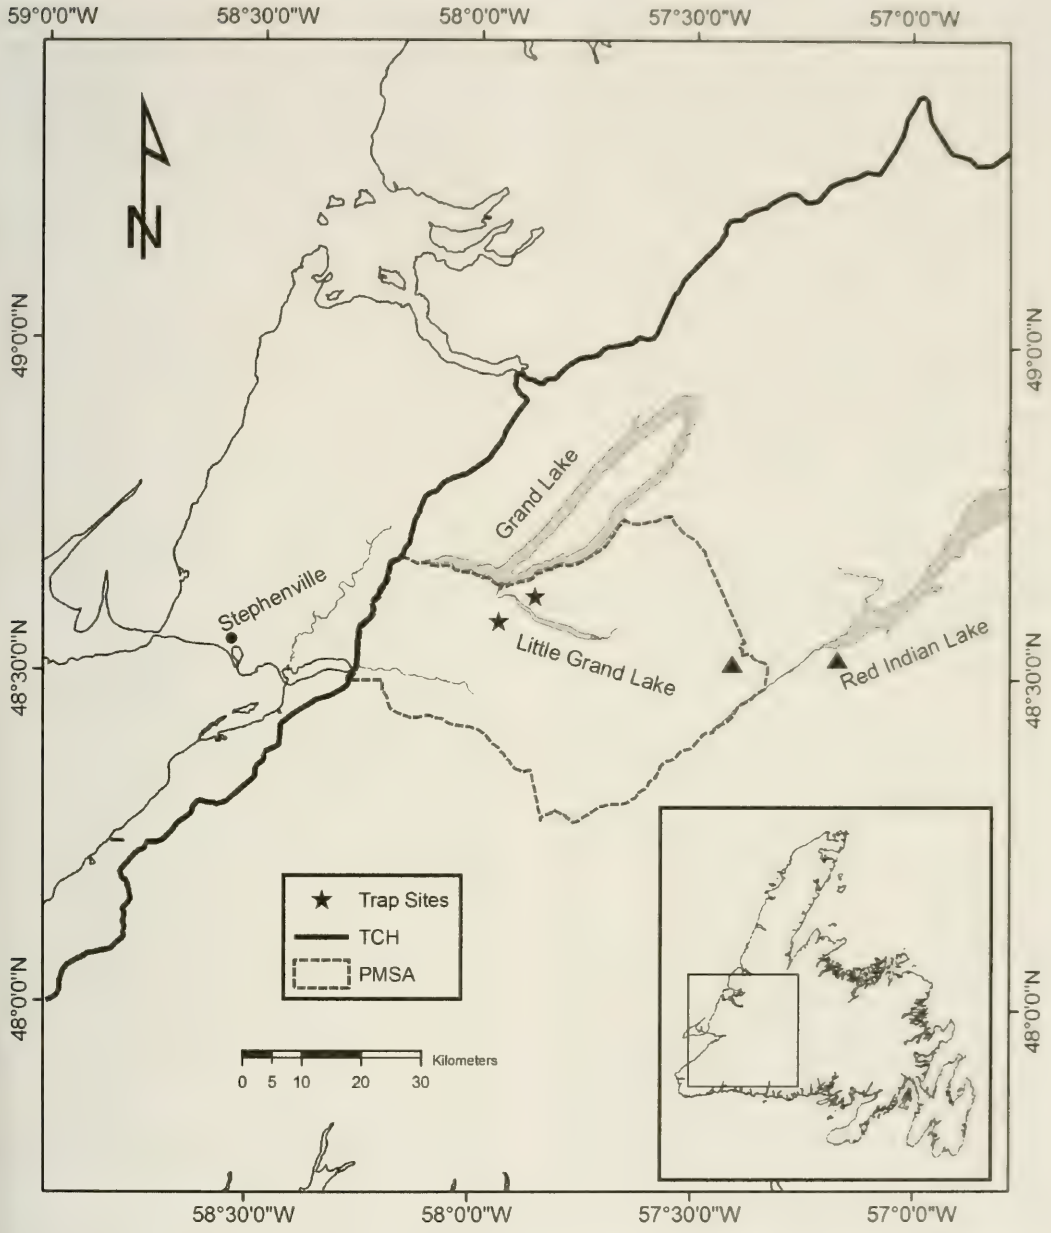

FIGURE 1. Map of southwestern Newfoundland showing location of Southern Red-backed Vole (*Clethrionomys gapperi*) captures in 1999, and capture sites relative to other areas mentioned in text; ▲ indicates location of first Southern Red-backed Vole capture in Red Indian Lake area in 2001. Inset map shows the location of areas relative to the island of Newfoundland.

graphic parameters is statistically broad, and many site-specific factors (e.g., prey availability, habitat patchiness, habitat selection under foraging versus predation-risk trade-offs), influence home-range characteristics and carnivore density.

Newfoundland Marten have been geographically and reproductively isolated from mainland Marten populations for the last 7000 years (South 1983), resulting in a genetically distinct subspecies amidst a much more genetically homogenous Canadian main-

land population (Kyle and Strobeck 2003). Additionally, Newfoundland Marten are large (males = 1254 g, n = 122; B. J. Hearn, unpublished data), and have extremely large home-range requirements (males = 30.8 km^2, n = 43; B. J. Hearn, unpublished data) compared with nearby mainland populations in Quebec (males = 937 g, n = 67; 7.4 km^2, n = 40; Potvin and Breton 1997) and Maine (males = 776 g, n = 23, Katnik 1992; 4.04 km^2, n = 96; Payer 1999). Collectively, these population characteristics suggest that the Newfoundland Marten is a product of a unique ecological setting and evolutionary selective factors operating on a geographically and reproductively isolated island population. Thus, it seems unlikely, given the historical ecological setting, that Newfoundland Marten spatial requirements evolved to access or select habitat (Hearn et al. 2005*) based on utilizing small mammals as prey.

We predict that the establishment of the Red-backed Vole on the island of Newfoundland will cause direct and indirect community-level effects in general and for Newfoundland Marten in particular (e.g., increased utilization of the Red-backed Vole as prey by Newfoundland Marten and Red Fox and associated demographic responses and interactions, more restricted habitat utilization by Newfoundland Meadow Voles, and changing utilization and dispersal of seeds by introduced Red-backed Voles and consequently changing plant regeneration patterns). The direct and indirect effects of previous introductions of non-native species to the island of Newfoundland have been previously described for predator–prey interactions (Bergerud 1971, 1983), plant successional patterns (Thompson et al. 1992, Thompson and Curran 1993), and species interactions (Benkman 1993).

Additional small mammal field surveys are being conducted to document the changing distribution of Red-backed Voles on the island and may offer additional information about the mechanism by which this species was introduced. In this regard, genetic analysis may be helpful in determining the source population for this introduction. Future field studies, in areas where Newfoundland Marten spatial characteristics have been well documented (Hearn et al. 2005*) are being considered to assess the effects of this new prey species on Newfoundland Marten population characteristics.

Acknowledgments

Funding for this work was provided by Natural Resources Canada, Canadian Forest Service; the Newfoundland and Labrador Department of Environment and Conservation – Inland Fish and Wildlife Division; Newfoundland and Labrador Department of Forest Resources and Agrifoods – Forestry Division; Corner Brook Pulp and Paper; Abitibi Consolidated; and the Western Newfoundland Model Forest through support of a five-year research project concerning Newfoundland Marten. Landriault, L. J., M. N. Hall, J. Hamr, and F. F. Mallory. 2006. Long-range homing by an adult female Black Bear, *Ursus americanus*. Canadian Field-Naturalist 120(1): 57–60.

An adult female Black Bear was repeatedly captured and relocated as a result of nuisance behaviour. The relocation distances ranged from 40 km to 389 km (mean = 152 km, $n = 6$). She homed successfully from all relocations, even when accompanied by young-of-the-year. Differential homing ability among bears may depend on first homing from a short relocation, facilitating subsequent responses to longer distance relocations.

Key Words: Black Bear, *Ursus americanus*, homing, distance, relocation, translocation, Ontario.

The ability of animals to return home when removed from familiar territory has been recorded for several different species including: pigeons, *Columba* spp. (Papi 1992); Deer Mice, *Peromyscus maniculatus* (Bovet 1968; Teferi and Millar 1993); Red Squirrels, *Tamiasciurus hudsonicus* (Bovet 1995); Raccoons, *Procyon lotor* (Belant 1992); Wolves, *Canis lupus* (Fritts et al. 1984); and Brown Bears, *Ursus arctos* (Miller and Ballard 1982). The use of relocation as a management tool for nuisance bears has provided researchers with the opportunity to study the homing behaviour of a large mammal. Several studies conducted on Black Bears (*Ursus americanus*) have determined that a high proportion of relocated bears return to the capture area (Harger 1970; Alt et al. 1977; Rutherglen and Herbison 1977; McArthur 1981; Rogers 1986a; Shull 1994), with adult bears more likely to return to the capture area than juveniles (Harger 1970; Rogers 1986a; and Landriault 1998). During a four-year study of relocated nuisance Black Bears in Sudbury, Ontario (46°N, 81°W), one bear was successful in homing over an exceptionally long distance (Landriault 1998). This report describes her relocation and homing history, and briefly discusses factors that may affect homing success in relocated bears.

Animals were captured in large barrel traps or with the use of immobilization agents delivered via a dart gun or jab stick. In accordance with the study protocol, nuisance Black Bears were immobilized using a mixture of ketamine hydrochloride (Ketaset®) and xylazine hydrochloride (Rompun®) at a dosage of 4.4 mg/kg and 2.2 mg/kg, respectively. Captured bears were weighed, various body measurements obtained, and the animals were ear-tagged (Kurl-lock metal tags, Ketchum Manufacturing Inc, Brockville, Ontario). A premolar was extracted for ageing purposes. Some animals were fitted with a very high frequency (VHF) radio-transmitter collar (148 to 152 MHz range, Lotek Inc., Newmarket, Ontario). If re-captured, most bears were immobilized again to assess changes in condition by means of growth rates for juveniles and changes in weight for adults. The majority of capture and release locations were estimated using topographical maps or a hand-held global positioning system (GPS) unit; however, the only information available for the first and third captures described in this note was the township name. In these cases the center of the township was used to estimate release and homing distances. In the study area, townships were 10×10 km such that the center of the township could only be a maximum of 7 km from the true location. Distances presented in this report are straight-line measurements and do not take topographical features into consideration. Returning within 20 km of the capture site was defined as successful homing (Landriault 1998).

Adult female Black Bear LR04 was captured as a nuisance animal and relocated a total of 6 times (Table 1 and Figure 1). In all cases she was captured because she was foraging in improperly stored refuse at residences in suburban areas. She was initially captured as a nuisance animal in June of 1994. At this time, she was estimated to be 9 years of age based on the examination of premolar cementum annuli (Johnston et al. 1987). She was ear-tagged and relocated approximately 40 km south of the capture site. LR04 was recaptured in June of 1995, an estimated 6 km from her first capture location. She was lactating; however, no cubs were found. She was fitted with a radio-collar and relocated a second time, 105 km to the north. LR04 was subsequently recaptured in September of 1995, 7 km from her second capture location, and was accompanied by three cubs. The four bears were relocated as a family unit, approximately 112 km. LR04 was captured again in June of 1996, within 17 km of her previous capture location, accompanied by three yearlings. LR04 and two of the yearlings were relo-

TABLE 1. Relocation history of nuisance Black Bear LR04, including relocation distance, bearing, and proximity of consecutive capture and release sites. All capture locations are in the suburban areas of the City of Sudbury, Ontario. Body weight information has been included as a means to assess the general condition of the animal.

Capture date	Body weight (kg)	Proximity of capture site to previous capture site (km)	Relocation distance (km)	Proximity of release site to previous release site (km)	Bearing to relocation site
20 June 1994	65		40		166°
14 June 1995	76	6	105	141	325°
18 September 1995	147	7	112	6	325°
8 June 1996	67	13	166	76	343°
5 July 1996	82	10	389	222	330°
1 October 1997	140	< 1	100	290	323°

cated 169 km. LR04 was subsequently captured a fifth time in July of 1996, within 11 km of her previous capture site. She was not accompanied by any offspring. On this fifth relocation she was transported 389 km to the northwest and was recaptured in October of 1997, within 7 km of her previous capture location. At this time she weighed approximately 140 kg and was relocated 100 km.

From 1994 to 1997, adult female LR04 was relocated a total of six times, with relocation distances ranging from 40 to 389 km. She homed successfully in all cases and the maximum distance between any two capture sites was 10 km. The longest homing distance observed for this animal (389 km) appears to be a record distance for Black Bears. The true distance travelled by bear LR04 to return to her home range is expected to be much greater than 389 km, due to variations in topography and the probable deviations from straight-line homing as a result of landscape features, human habitation, foraging, and interactions with other animals. Other observations of long-range homing in relocated Black Bears include animals returning from distances of 99 km (Rutherglen and Herbison 1977) and 229 km (Harger 1970) on the Upper Peninsula in Michigan, 103 km in the Rocky Mountains of British Columbia (Erickson and Petrides 1964), and 182 km in Central Ontario (Landriault 1998). Although all of these observations are from adult animals, in some instances juveniles can home from long distances. As part of the same study, a juvenile female homed from a relocation distance of 92 km (Landriault 1998). The differential homing ability of adults versus juveniles has been attributed to an established home range and to experience gained during seasonal foraging excursions (Anderson et al. 1977; Rogers 1986b, Rogers 1987a).

Juvenile male Black Bears generally disperse between 2 and 4 years of age, prior to establishing home ranges. In contrast, juvenile females generally take up residence in their maternal home range (Rogers 1987b; Schwartz and Franzmann 1992). It has been hypothesized that bears without established home ranges have limited homing success due to a lack of effort rather than ability (Anderson et al. 1977; Rogers 1986b). As predicted by this hypothesis, lower homing success has been observed in juvenile males than in adults and juvenile females (Harger 1970; Rogers 1986a; and Landriault 1998). Adult females would benefit from a strong desire to return to their established home range where they have been able to meet the nutritional requirements necessary for reproduction (Rogers 1976; LeCount 1982; Elowe and Dodge 1989; Kolenosky 1990) and have successfully avoided fatal conflicts for them and/or their young, with local conspecifics (Jonkel and Cowan 1971; Tietje et al. 1986).

Experience would also be expected to increase an animal's homing success. Many Black Bears cover extensive area during yearly foraging excursions (Rogers 1987a) and these foraging excursions may allow bears to develop orientation and homing skills, resulting in increased homing success with age. Many young bears may not have gained enough experience to home successfully from significant distances.

It is unknown whether bear LR04 would have homed from 389 km had she been relocated that distance after her initial capture. It is possible that repeated relocations result in training individual bears to home from long distances. Black Bears that home successfully after the first relocation are likely to be successful after all subsequent relocations of increasing distance (Blanchard and Knight 1995; Landriault 1998), suggesting that homing ability in bears is enhanced with experience. Homing pigeons are commonly trained by gradually increasing the displacement distance from the home loft, and young birds displaced too far early in their training do not home successfully (Papi 1992). The successful return from a relatively short distance appears to enhance homing effort and/or skill, and increases the chance of success from longer distances.

The desire for adults to return to an established home range, combined with experience acquired in navigating over long distances, appears to explain why adult bears are more adept at homing. The inadvertent training of bear LR04 by gradually increasing the reloca-

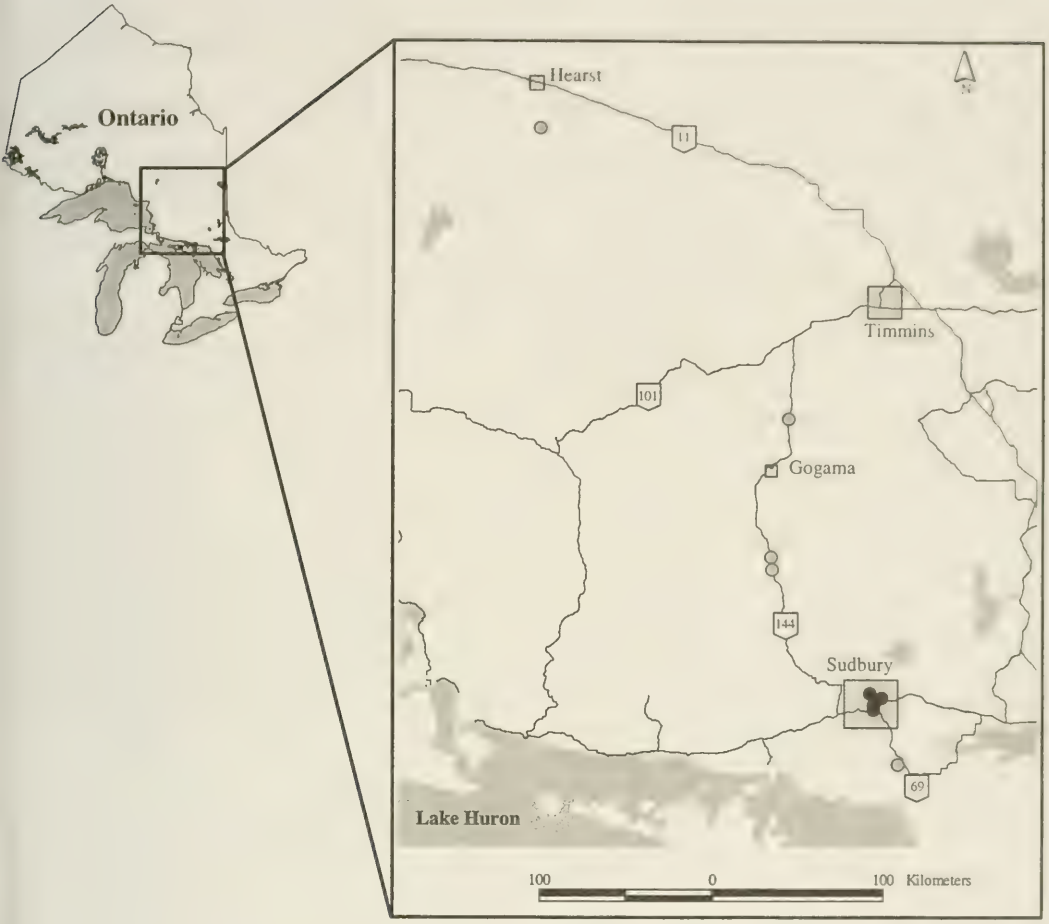

FIGURE 1. Capture and release locations for nuisance Black Bear LR04. Black circles represent the capture locations and grey circles represent release locations. The thin black lines on the map correspond to the two-lane paved provincial highways along the relocation routes, while the shaded squares are cities and small towns along these routes. Irregular shaded areas are lakes.

ion distances may explain how she was able to home successfully over a longer distance than any previously reported for a Black Bear.

Bryan, Heather M., Chris T. Darimont, Thomas E. Reimchen, and Paul C. Paquet. 2006. Early ontogenetic diet in Gray Wolves, *Canis lupus*, of coastal British Columbia. Canadian Field-Naturalist 120(1): 61-66.

Within populations, different age classes often consume dissimilar resources, and provisioning of juveniles by adults is one mechanism by which this can occur. Although the diet of Gray Wolves (*Canis lupus*) has been studied extensively, the diet of pups is largely unknown. We examined faeces deposited by altricial pups and adult providers during the first two months following birth at two den sites over two years on the central coast of British Columbia, Canada. Pups and adult wolves consumed similar species, and Black-tailed Deer (*Odocoileus hemionus*) constituted most of the diet for both age groups. Pup and adult diet, however, diverged. Specifically, adult deer occurred significantly less frequently in the diet of pups than in the diet of adult wolves, which suggests that adults selectively provisioned pups. We speculate that this may relate to adaptive strategies of adult wolves to provide their offspring with food of optimal nutritional value or reduced parasitic burden, and or logistic factors associated with provisioning such as prey transportability and availability.

Key Words: Gray Wolf, *Canis lupus*, Sitka Black-tailed Deer, *Odocoileus hemionus*, provisioning, pups, diet, British Columbia.

Different age classes within a species often consume dissimilar resources, increasing population niche width and decreasing intraspecific competition (Polis 1984; Bolnick et al. 2003). Provisioning of young by adults is one mechanism whereby differences in diet between young and adults may occur (Markman et al. 2002). Foragers that select foods to optimize growth and development of their offspring may have a selective advantage over those that provision their young opportunistically (Krebs and Avery 1984; Wright et al. 1998). Providers may select resources that are easy to transport (Molsher et al. 2000) or that have nutritional qualities important for developing juveniles (Krebs and Avery 1984). Furthermore, providers may alter their behaviour while rearing young to reduce exposure of their offspring to parasites (Christe et al. 1994; Merilä and Allander 1995; Tripet et al. 2002).

Young Gray Wolves (*Canis lupus*) rely predominantly on food killed and delivered by closely related adult providers for many months (Paquet and Carbyn 2003). Although diets of adult wolves have been studied extensively, the diet of juvenile wolves has not been well documented in any system (Paquet and Carbyn 2003).

Wolves of coastal British Columbia (BC) have a potential niche that includes up to 15 mammal species (Darimont and Paquet 2000*, 2002; Darimont et al. 2004), which likely differ in transportability, nutritional characteristics, and parasite load. Herein, we investigated potential age class differences in diet by examining faeces of pups and adults deposited at den sites within the first two months following birth for two social groups over two breeding seasons. Our objectives were to describe the diet of adult and juvenile wolves during the denning season and examine whether the diet of pups differed from that of adults. Given the ubiquity of evidence from a variety of other systems, we predicted that adult wolves would selectively provision food resources to developing pups.

Study Area

We collected faeces from two home sites (i.e., reproductive areas) on the central coast of British Columbia in July of 2001 and 2002. The study area has been described well elsewhere (Darimont and Paquet 2002; Darimont et al. 2004). One site was located on Chatfield Island (area: 48 km^2; distance from mainland: 1 km; centre island location: 52°16'N, 128°05'W) and the other on Yeo Island (98 km^2; 0.25 km; 52°21'N, 128°08'W). Both sites were <100 m ASL (above sea level). During the study, social groups were composed of 3-7 pups and 3-8 adults. Potential prey species include Sitka Black-tailed Deer (*Odocoileus hemionus sitkensis*), mustelids, ursids, birds, rodents, fish, and marine mammals and invertebrates (Darimont and Paquet 2000*, Darimont et al. 2004).

Materials and Methods

Scat collection and analysis

Both sites were on or within 50 m from transects monitored for faeces during spring (April/May) before arrival of wolves or birth of pups, and summer (July) after wolves had left the areas. Thus, we are confident that faeces collected during July represent resources

acquired during May and June, at which time pups were approximately 2-8 weeks old. This period also corresponds to the birth pulse of many prey in the area, including deer (Shackleton 1999).

In all cases, wolves had moved to another site by July, so we sampled all or most faeces that surrounded the abandoned sites (within ~100 m). Based on diameter, we subjectively classified faeces (n = 479) as those deposited by pups or adults. In July, pup faeces are easy to distinguish from those of adults and there is no overlap in diameter (Weaver and Fritts 1979). The few faeces that were mostly liquid or suggestive of severe weathering (i.e., amorphous shape or irregular surface; n ~ 20), which we felt could not be accurately classified, were discarded.

Faeces were autoclaved, washed, and dried so that only macroscopic components such as hair, bone, teeth, and hooves remained (Cuicci et al. 1996). To identify mammalian prey items, we examined the entire sample with the naked eye to detect hair clumps that differed in colour, size and/or texture from others, and other clues such as teeth, claws and hooves. Subsequently, we microscopically examined five sub-samples, randomly selected via a grid system in the sample tray, which typically contained five to 10 hairs each. We identified species by comparing with a reference hair collection, as well as cuticular scale imprints using dissecting and compound microscopes and dichotomous keys (Mayer 1952; Adorjan and Kolenasky 1969). We differentiated between adult deer and fawn hair using a combination of diameter and colour characteristics (Scott and Shackleton 1979). Birds and invertebrates were identified by feathers, claws, shell fragments, and cuticles and were scored as present or absent. Using an 8 × 10 grid of 1-cm squares, we estimated the percentage of prey species in each faeces.

All faeces were analyzed by one observer (HB) to eliminate inter-observer bias (Spaulding et al. 2000). Before faecal analysis, we tested observer accuracy with a reference collection and scored 92% (23 out of 25 correct). Following identification of prey remains, we also assessed precision and scored 100% (25/25) on classification of taxa. Finally, we investigated our precision in assessing adult/fawn categorization. We classified 77% (17/22) correctly. This bias, however, was directional: we scored five adults incorrectly as fawns.

Data analysis

We used two indices in analysis. Percentage of whole scat equivalents (pWSE) is the mean percentage of each prey species found per faeces (Angerbjörn et al. 1999; Elmhagen et al. 2002). For example, two faeces containing deer and seal in percentages of 40,60 and 60,40 respectively, would have pWSE of 50 for both prey species. Percent occurrence per item (O/I) is the number of occurrences of each prey species divided by the total number of items identified, where an item is defined as an occurrence of a prey species in an individual faeces (Theberge et al. 1978).

We used log-linear analysis on pWSE data to test for differences in diet between pups and adult wolves while simultaneously assessing influences of years and sites. We excluded birds and invertebrates from this analysis because conversion to pWSE was not possible on presence/absence data. These items occurred infrequently and were never found alone in faeces. In this log-linear analysis, we also combined non-deer items into an "other" category due to infrequent occurrence (see Results).

To measure dietary breadth of both age classes, we used Levin's Measure, standardized on a scale from 0 to 1 (Hurlbert 1978; Krebs 1999; Elmhagen et al. 2002). Levin's measure of dietary breadth, B_A, is calculated using pWSE data as follows:

$$[1] \qquad B_A = \left[\frac{1}{\sum p_i^2} - 1\right] \Big/ (n-1)$$

where p_i is the proportion of resource i in a diet consisting of n resources.

We also calculated dietary overlap between age classes using Schoener's measure (p_{jk}; Shoener 1970) and Horn's index (R_o; Horn 1966). Both calculations indicate food-niche overlap between populations j and k, where p_{ij} and p_{ik} are the proportions of resource i in diets, and n is the number of available resources. Although Shoener's measure is frequently used and therefore comparable to other literature, Horn's index is less biased under changing numbers of resources, sample size, and resource evenness (Krebs 1999). Calculations were performed on pWSE data.

$$[2] \qquad p_{jk} = \left[\sum^{n} (\text{minimum } p_{ik}, p_{ij})\right] 100$$

$$[3] \qquad R_o = \frac{\sum (p_{ij} + p_{ik}) \log (p_{ij} + p_{ik}) - \sum p_{ij} \log p_{ij} - \sum p_{ik} \log p_{ik}}{2 \log^2}$$

Results

Pup and adult wolves consumed a breadth of resources; however, Sitka Black-tailed Deer constituted most of the diet for both age classes (Table 1). Deer represented 54.6 to 100% of whole scat equivalents, depending on site and year, and accounted for 50.0 to 98.4% of all prey items (Table 1). After deer, Harbour Seal (*Phoca vitulina*), invertebrates, and birds were the most common prey items, whereas Beaver (*Castor canadensis*), Short-tailed Weasel (*Mustela ermina*), Mink (*Mustela vison*), River Otter (*Lutra canadensis*), Marten (*Martes americana*), and Fisher (*Martes pennati*) occurred infrequently in the diets of pups and adult wolves (Table 1). Pups and adults had

Table 1. Prey items identified in the feces of pup ($n = 240$) and adult ($n = 239$) wolves from home sites on Chatfield and Yeo Islands, coastal British Columbia in 2001 and 2002. pWSE is proportion of whole scat equivalents, where *n* represents the number of whole scat equivalents. O/I is percent occurrence per item, where *n* represents the number of items in all feces. Invertebrates are marine invertebrates (e.g., crabs, bivalves). Categories with zero prey items are represented by (–).

similar dietary breadths (Table 2). Average percent dietary overlap between pup and adult wolves was 79%, whereas Horn's index showed a considerably higher average dietary overlap of 0.96 (Table 2).

A major difference between pup and adult diet was the proportion of different age classes of deer consumed. Pups consumed a lower proportion of adult deer and a higher proportion of fawn compared with adults (Partial $\chi^2 = 17.77$, df = 2, $P<0.001$; Table 1). The magnitude of this difference varied across years and locations (association between location, age class of wolf, and prey item; Partial $\chi^2 = 7.73$, df = 2, $P = 0.02$; Table 1). A high proportion of seal on Chatfield Island in 2001 caused the 3-way association (Table 1). Accordingly, when we excluded seal from log-linear analysis, the association between location, age class of wolf, and prey item was not significant (Partial $\chi^2 = 0.20$, df = 1, $P = 0.65$). We then found, similar to other areas and years, that pups consumed a significantly smaller proportion of adult deer than did adult wolves at both locations (Partial $\chi^2 = 17.91$, df = 1, $P<0.001$).

Discussion

A large body of literature exists regarding wolf diet but it primarily addresses spatial and temporal patterns (Paquet and Carbyn 2003; Peterson and Cuicci 2003) and not other aspects of intrapopulation variability. Relatively little dietary information exists in the context of raising young. Exceptions include two studies that found significant differences in the diet of adult wolves between den sites and nearby areas (Theberge et al. 1978; Meleshko 1986). Neither study, however, differentiated between pup and adult diet as we do here.

Herein, we show that juvenile and adult wolves from two coastal islands have similar niches at the prey species level, as they have similar dietary breadth and moderate overlap. These results show that adult wolves provide pups with food items similar to themselves and are not hunting distinct prey species for pups. At a finer resolution, however, we show that diets differ between pups and adults, which we infer as evidence for selective provisioning. Controlling for location and year effects, our log-linear results showed that pups were supplied a smaller proportion of adult deer than consumed by adults.

The difference we detected could be influenced by limitations in prey identification methods. Results of our precision test show a possible directional bias in categorization of deer age class towards fawns. The direction (or magnitude) of the difference between pup and adult diet, however, would not be affected and thus we consider this possible bias unimportant. Regardless, this demonstrates the importance of testing for, and reporting on, precision (and accuracy), which is extremely rare in dietary studies on wolves or other taxa (cf. Fritts and Mech 1981; Cuicci et al. 1996; Darimont et al. 2004).

TABLE 2. Dietary breadth and overlap as inferred by fæcal collection from den sites of pup and adult Gray Wolves, coastal British Columbia, summers 2001 and 2002.

	Chatfield Island		Yeo Island		Average
	2001	2002	2001	2002	
Dietary breadth

Dietary overlap					
Percent Overlap	79	79	72	86	79
Horn's Index	0.95	0.97	0.93	0.98	0.96

Selective provisioning occurs if diets of providing adults and altricial young differ, and evolves when the behavior is advantageous for reproduction or survival. Well-described in birds (e.g., Martin 1987; Wright et al. 1998), we suspect this behaviour is common in wolves and potentially other mammals. Although we have no data to indicate why adult wolves selectively provision pups, several "logistic" and adaptive explanations are plausible.

While likely rooted in adaptive value, provisioning strategies probably are shaped further by logistic or environmental factors that affect the relative benefits and costs of providing care to young. First, adults may selectively provision resources such as whole fawns or portions of fawns because they are easy to transport to young (e.g., Molsher et al. 2000). Ease of transport may be particularly important when pups are old enough to consume solid prey items. Other important factors affecting wolf foraging, and subsequent provisioning, are spatial and temporal variation in prey abundance (e.g., Theberge et al. 1978; Meleshko 1986), which would then interact with how pack members divide the provisioning labour. Contributions to young by each member would depend on age, experience, hunting habits, social status, and genetic relatedness to offspring (Mech et al. 1999). For example, pup diets could be biased if individual wolves such as the mother or father target fawn and provision at a higher frequency than other pack members.

Among several adaptive hypotheses, we speculate that parents may base provisioning decisions on nutritional requirements of developing young. For example, protein is important for growing animals (Robbins 1993) and may be particularly important in large carnivores such as wolves (Lauer et al. 1969). If protein content drives provisioning, then a greater proportion of high-protein resources would be expected in the diet of young wolves. Based on published values, there is no difference in protein content between age classes of deer (Percent body weight = 20.3 for both fawn [$n = 7$], and adult [$n = 16$] White-tailed Deer, *O. virginianus*; means calculated from Robbins 1973). This suggests that protein is not a driving factor in provisioning we observed.

Differences in body fat among prey might contribute to adaptive provisioning behaviour. Body mass, which is often associated with consumption of fatty resources in large mammals, is important for survivorship for both providers and offspring (Derocher and Stirling 1996). Of major prey items in this study, seal had the highest fat content (percent body weight = 23.6 [$n = 35$], Harbour Seal; Coltman et al. 1998) followed by adult deer (Percent body weight = 12.8, [$n = 16$], White-tailed Deer; mean calculated from Robbins 1973) fawn (percent body weight = 3.1 [$n = 7$], White-tailed Deer; mean calculated from Robbins 1973). Although pups consumed more high-fat prey items (seal) than adult wolves on Chatfield Island in 2001, they consumed less high-fat prey items (adult deer) than adult wolves at all locations. This suggests that adult wolves may provide their young with high-fat food only when there is an abundance of high-fat prey items. Otherwise, it is possible that adults may be selectively retaining prey items of higher fat content, which may represent a benefit controlled by provisioners in what potentially is a parent-offspring (or in this case, provider-receiver) conflict (Trivers 1974).

Wolves may provision according to potential parasite load in prey, which may provide the best adaptive explanation for the pattern we observed. As ungulates and other animals age, their parasite burden often increases (Crooks et al. 2001). Increasing prevalence of parasitic infection with age has been found in White-tailed Deer (Bogaczyk et al. 1993), Marsh Deer (*Blastocerms dichotomus*), and Pampas Deer (*Ozotocerus bezarticus;* Ferreira et al. 1997). Although we could not find similar studies on black-tailed deer, we postulate that comparable disease dynamics occur in this species.

Many studies have shown that parasites are important in parental care strategies (Christe et al. 1994; Merilä and Allander 1995; Moreno et al. 1999; Tripet et al. 2002). Young animals have naive immune systems, as they have not been exposed to a wide variety of pathogens (Hutchings et al. 2002). Low levels of exposure to pathogens can help young develop immunity but high levels can have severe consequences on survival. Therefore, gradual introduction of pathogens

to young animals by providers is likely important, which an early diet biased towards fawns may achieve.

Avoiding excessive exposure to parasites may be particularly important in wolves, given their life history. Wolves are k-selected organisms, investing considerably in relatively few offspring. Furthermore, populations demonstrate a type I survivorship curve. Survival in pups, although not well studied, is thought to be typically lower compared with resident adults (Fuller et al. 2003). Pup mortality is often related to or influenced by diseases, many of which exploit prey as intermediate hosts (Kreeger 2003).

Future studies could address logistic and adaptive hypotheses we have presented herein and their possible interaction. In summary, we suggest that selective provisioning strategies should now be considered among the behaviours of wolves and one that contributes to maximizing lifetime reproductive output.

Acknowledgments

This study took place in Heiltsuk Traditional Territory, and we thank them for their support and involvement. We are grateful to the Raincoast Conservation Society for financial and logistical support as well as to A., J., and R. Bryan, H. Down, J. Gordon-Walker, J. Havelaar, D. Klinka, I. and K. McAllister, G. Pfleuger, M. Price, R. Ring, M. Spoljaric, C. Starr, and N. Winchester. The McCaw Foundation, National Geographic Society, Wilburforce, Vancouver Foundation, World Wildlife Fund Canada, and private donors kindly provided funding. While preparing the manuscript, CTD was supported by a Natural Sciences and Engineering Research Council (NSERC) – Industrial Postgraduate Scholarship.

Extension of Coyote, *Canis latrans*, Breeding Range in the Northwest Territories, Canada

H. Dean Cluff

Environment and Natural Resources, Government of the Northwest Territories, P.O. Box 2668, Yellowknife, Northwest Territories X1A 2P9 Canada

Cluff, H. Dean. 2006. Extension of Coyote, *Canis latrans*, breeding range in the Northwest Territories, Canada. Canadian Field Naturalist 120(1): 67-70.

Coyotes (*Canis latrans*) have resided in the Northwest Territories for several decades but have only rarely been sighted north of Great Slave Lake (>62° N. latitude) in the Taiga Shield ecozone. Records show Coyotes have been seen since the 1960s. Prior to 2000, evidence of Coyotes breeding in the Taiga Shield has been anecdotal. In 2000, a Coyote was repeatedly seen at the Yellowknife airport and in 2001, a pair of Coyotes was observed with two pups. Since then, Coyote pups have been observed annually at the airport and adult Coyotes are seen regularly within the city of Yellowknife, an urban island within the Taiga Shield ecozone. Unlike in most regions occupied by Coyotes, medium-sized prey are rarely seen. Recently, Coyotes have become a potential hazard to aircraft at the Yellowknife airport. Although Coyotes appear to have established themselves within the city of Yellowknife, maintaining a presence beyond the urbanized area remains uncertain.

Key Words: Coyote, *Canis latrans*, distribution, range extension, reproduction, Northwest Territories.

Coyotes (*Canis latrans*) have been uncommon in the Northwest Territories (NWT) north of Great Slave Lake (north of the 62nd parallel). Banfield (1974) and Voigt and Berg (1987) suggested Coyote distribution was limited to the Taiga Plain ecozone and did not extend beyond the northwest shore of Great Slave Lake where the Taiga Shield ecozone begins. The Taiga Shield ecozone is characterized by a patchwork of wetlands, forests, meadows, and shrublands situated on top of glaciated bedrock with numerous lakes and rock outcrops. Summers are short and winters are long and cold. Although sightings of Coyotes beyond current range limits may be expected, occurrences of reproduction beyond the Taiga Plain and into the Taiga Shield would be less likely. Bekoff (1977) and Bekoff and Gese (2003) estimated the range of Coyotes to be further northward but their delineation appears based on the northern limit of trees ("tree-line"). This paper reports on recorded sightings and breeding of Coyotes in the Taiga Shield ecozone in northwestern Canada. I identify current conflicts and management responses for Coyotes as their numbers have increased in a northern urban area.

Methods

I recorded and investigated Coyote sightings in the Yellowknife area since summer 2001. I solicited sighting and harvest information from wildlife officers, hunters, and trappers in the Northwest Territories and western Nunavut. I searched historical records for Coyotes among fur harvest records, Wolf (*C. lupus*) bounty receipts, and annual reports. Carcasses of Coyotes obtained since 2001 were examined whenever possible.

Results and Discussion

The earliest recorded sighting of Coyotes in the Taiga Shield ecozone occurred in the Yellowknife area in the early 1960s. In winter 1974-1975, five Coyotes were observed in the Long Lake area near the Yellowknife airport (J. Hordal, Hay River, Northwest Territories, personal communication). Prior to 2000, three other sightings occurred outside (>40 km) of the Yellowknife area (Figure 1) and in the late 1960s, a trapper shot a Coyote on Stark Lake, east from Lutsel K'e (formerly Snowdrift) (A. Boucher, Lutsel K'e, Northwest Territories, personal communication). One Coyote was occasionally sighted at the Yellowknife airport in 2000 and in spring 2001, two adult Coyotes were often reported near the airport; two pups were observed later that summer, the first documented occurrence of Coyotes breeding this far north in the Northwest Territories.

There have been two oral reports of Coyotes at Kugluktuk (67°49'N, 115°06'W), Nunavut, near the northern coast of mainland Canada. Although exact dates and written reports are absent, the sightings are noteworthy as they occurred on the tundra 40-60 kilometres beyond the tree-line. The first was by a hunter who shot a Coyote 70 km west of Kugluktuk around 1988. The second was circa 1997 when two hunters saw a Coyote southwest of Bloody Falls on the Coppermine River (A. Niptanatiak, Kugluktuk, Nunavut, personal communication).

The presence of Coyotes at the Yellowknife airport is not surprising because the area is characterized by open grassy habitat in contrast to the surrounding boreal forest. Rodents, birds, hares, and other wildlife on the airport property serve as food. The availability of food

scraps near the city of Yellowknife proper and at the city dump should contribute to a continued presence by Coyotes within the urbanized area. It is possible that the Coyotes observed near the Yellowknife airport in winter of 1974-1975 had bred in the area as three of the five Coyotes did not appear adult size (J. Hordal, personal communication).

Coyotes in northern urban areas

The existence and colonization of Coyotes in and around Yellowknife is of concern to residents and airport authorities. Residents are primarily concerned for the safety of their pets. Airport authorities are concerned as Coyotes and their pups occupy the Yellowknife airport property and represent an air safety risk. In 2002, 2003 and 2004, 2, 7, and 4 pups were observed on the airstrip area respectively (S. Loutitt, Yellowknife airport, personal communication). Coyotes have not been limited to the airport. Seven were observed together on Back Bay in Yellowknife on 9 December 2004 (J. Bastedo, Yellowknife, personal communication) representing the largest number of Coyotes observed together within Yellowknife to date. In addition, a Coyote pup was found dead on 30 August 2004 (J. Bastedo, personal communication) and another Coyote pup was road-killed on 29 October 2004, both within Yellowknife city limits. Furthermore, on 21 October 2004, a Coyote pup was killed on the highway about 60 kilometres northwest of Yellowknife and may represent a separate litter (Figure 1).

The origin of this newest incursion of Coyotes is unknown, although they may have followed the single highway corridor connecting Yellowknife to the south. Coyotes have been expanding their range elsewhere over recent decades and human-induced habitat changes are likely contributory (Moore and Parker 1992; Chubbs and Phillips 2002; Chubbs and Phillips 2005). Factors that might discourage Coyotes from colonizing northward include morphology, behaviour, and reproduction (Phillips 1982). Although not morphologically equipped for travel in areas with deep snow, Coyotes might overcome this limitation by using trails and areas with hard snow (Murray and Boutin 1991; Murray and Larivière 2002). Wolves often kill coyotes where their ranges overlap (Krefting 1969; Paquet 1989; Crabtree 1998), further discouraging northern Coyote range expansion.

Air-strike risk

Coyotes at the Yellowknife airport present a public safety risk because of aborted take-off and landing attempts and potential for collisions causing property damage and personal injury (B. Webber, Yellowknife airport, personal communication). Although the airport perimeter is fenced, Coyotes can access the area through holes in the chain-link or by digging underneath. Continual removal efforts would be required to be effective over the long-term.

Although Coyotes have the potential to cause significant damage to small planes, those struck at southern airports are often hit by undercarriage and do little overall damage to the aircraft (Dolbeer et al. 2000; Cleary et al. 2004). The greater risk is from aborted take-off and landings (Dolbeer et al. 2000), as pilots tend to see Coyotes on runways before collisions occur.

There is anecdotal evidence that Coyotes may disperse other wildlife at airports such as Sandhill Cranes (*Grus canadensis*), Red Fox (*Vulpes vulpes*), and deer (*Odocoileus* sp.), and thus reduce the overall risk of wildlife strikes by aircraft (R. Dolbeer, United States Department of Agriculture, personal communication; S. Loutitt, personal communication). Coyotes are known to predate on Red Fox in some southern regions (Voigt and Earle 1983; Sargeant et al. 1987; Harrison et al. 1989), although fox predation by Coyotes has not yet been reported at the Yellowknife airport. There are few site-specific wildlife studies that address relative abundance and spatial patterns of wildlife at airports (Hoffman et al. 1996; Dolbeer et al. 2000). The dilemma at the Yellowknife airport is one of risk management. Airport management staff believe co-existence is possible and have chosen not to eliminate Coyotes but to monitor their presence and reduce numbers when required.

Coyote persistence

Whether Coyotes remain in the Yellowknife region is uncertain, although they occupy similar habitat elsewhere (e.g., Alaska; Labrador). Coyotes expanded their range northwest to Alaska in the late 1800s by scavenging along trails left by the gold rush (Gier 1975) and arrived in the Yukon by 1910 (Parker 1995). Coyotes appeared in the Northwest Territories fur harvest in the early 1930s when records were first kept. Suppressants to early colonization of Coyotes in the Yellowknife region include hunting, trapping, predation by Wolves, and incidental mortality at poison baits during Wolf control in the early 1960s (Heard 1983; Cluff and Murray 1995). Wolves are occasionally observed at the Yellowknife airport, and in 2004 a pack of five were reported within city limits.

To sustain a Coyote population a reasonable prey base must exist. Birds, Snowshoe Hare (*Lepus americanus*) and other small mammals would be the main source of food for forest-dwelling Coyotes (Crête et al. 2001). White-tailed Deer (*O. virginianus*) are only rarely sighted in the Taiga Shield (unpublished data; Veitch 2001). Wood Bison (*Bison bison athabascae*) have expanded their range into the area since 1999 but this may adversely impact Coyotes if Wolf numbers also increase. Garbage and domesticated animals in the Yellowknife area would augment the available food supply. The Yellowknife city dump, electrified only in summer against Black Bears (*Ursus americanus*), is not a barrier to Coyotes. Cabins and homes scattered on the landscape outside of Yellowknife may also supply

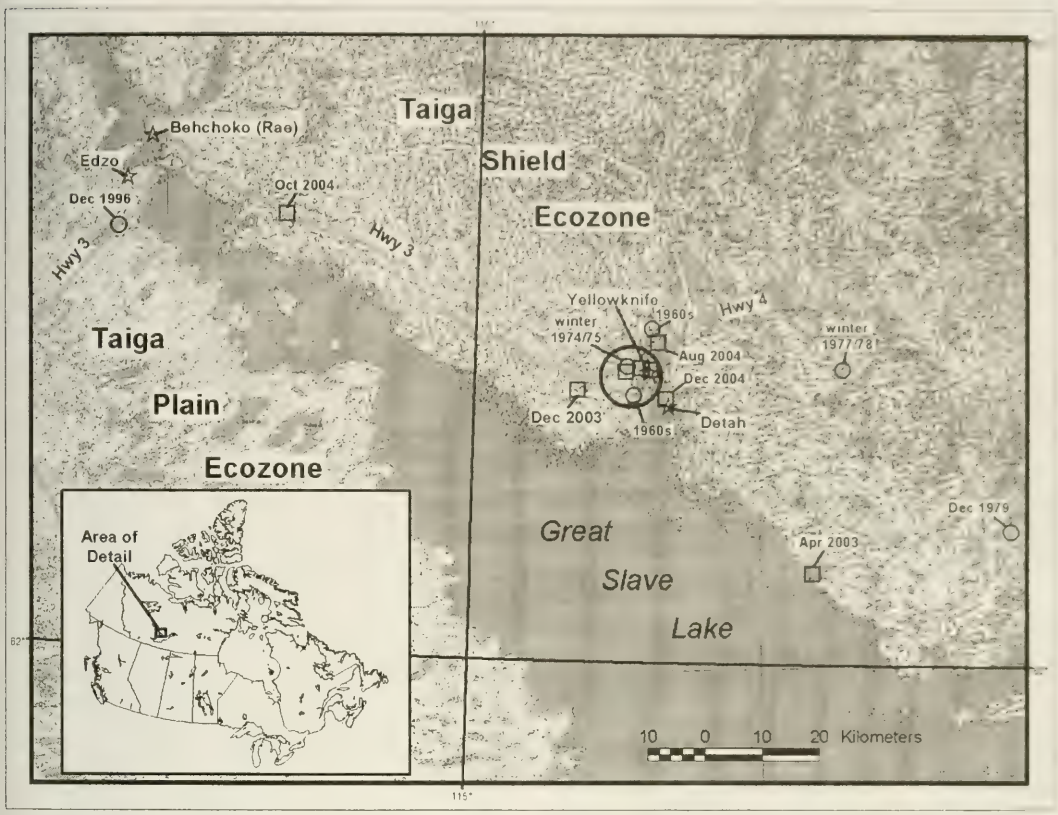

FIGURE 1. Taiga Plain and Taiga Shield ecozones bordering Great Slave Lake in the Northwest Territories showing records of Coyotes since the 1960s documented in text. Circles represent sites prior to 2000, squares in 2003 and 2004.

food. Consequently, Coyote persistence in Taiga Shield of the Northwest Territories may be strongly linked to a suburban environment, especially if an inadequate prey base exists elsewhere. How the public and wildlife management authorities choose to deal with Coyotes as urban carnivores will be a key factor for Coyote persistence in the Yellowknife region.

Acknowledgments

I thank the trappers, wildlife officers, and biologists in the Northwest Territories and Nunavut for their assistance in documenting and mapping sightings of Coyotes in the two jurisdictions. I also appreciate the efforts of airport management staff to document their sightings of Coyotes and to facilitate logistics of my investigations. E. Campbell was especially helpful in referring me to trappers and providing earlier personal sightings of Coyotes. Comments from A. Gunn, G. Elliott, M. Crête, and two anonymous referees helped improve an earlier version of the manuscript.

Adams, W. Eugene, Jr., Larry W. Kallemeyn, and David W. Willis. 2006. Lake Sturgeon, *Acipenser fulvescens*, movements in Rainy Lake, Minnesota and Ontario. Canadian Field-Naturalist 120(1): 71-82.

Rainy Lake, Minnesota-Ontario, contains a native population of Lake Sturgeon (*Acipenser fulvescens*) that has gone largely unstudied. The objective of this descriptive study was to summarize generalized Lake Sturgeon movement patterns through the use of biotelemetry. Telemetry data reinforced the high utilization of the Squirrel Falls geographic location by Lake Sturgeon, with 37% of the re-locations occurring in that area. Other spring aggregations occurred in areas associated with Kettle Falls, the Pipestone River, and the Rat River, which could indicate spawning activity. Movement of Lake Sturgeon between the Seine River and the South Arm of Rainy Lake indicates the likelihood of one integrated population on the east end of the South Arm. The lack of re-locations in the Seine River during the months of September and October may have been due to Lake Sturgeon moving into deeper water areas of the Seine River and out of the range of radio telemetry gear or simply moving back into the South Arm. Due to the movements between Minnesota and Ontario, coordination of management efforts among provincial, state, and federal agencies will be important.

Key Words: Lake Sturgeon, *Acipenser fulvescens*, biotelemetry, Rainy Lake, Ontario, Minnesota.

Movement patterns of Lake Sturgeon (*Acipenser fulvescens*) were relatively unstudied through the early 1970s (Scott and Crossman 1973). However, in the past decade, Lake Sturgeon movements have been studied at an increasing rate throughout much of the species' range (Rusak and Mosindy 1997; McKinley et al. 1998; Auer 1999; Borkholder et al. 2002; Knights et al. 2002). Lake Sturgeon have been found to move large distances for purposes such as spawning (Threader and Brosseau 1986; Fortin et al. 1993; Rusak and Mosindy 1997; Auer 1999) while maintaining smaller ranges in other systems (Bassett 1982*). Such movement patterns make Lake Sturgeon management difficult, particularly for multiple agencies dealing with border waters of substantial size.

Rainy Lake, a border water shared by Minnesota and Ontario, contains a Lake Sturgeon population that has gone largely unstudied. Lake Sturgeon in this system have been segregated from upstream Namakan Lake and downstream Lake of the Woods/Rainy River system populations by dams constructed on the outlets of Rainy and Namakan lakes early in the 20th century. The Lake Sturgeon is a Minnesota state-listed species of special concern (Minnesota Department of Natural Resources 2003*), while The Committee on the Status of Endangered Wildlife in Canada considers western populations of Lake Sturgeon to be endangered and the Rainy River-Lake of the Woods populations to be of special concern (Environment Canada 2005*).

Management of the Lake Sturgeon population in Rainy Lake is a cooperative effort among the Ontario Ministry of Natural Resources, the Minnesota Department of Natural Resources, and the United States federal government. Movement of Lake Sturgeon across international borders leads to an increase in importance of appropriate harvest regulations and an understanding of movement patterns and spawning locations. Such information will allow managers to protect areas that are important for Lake Sturgeon spawning.

The objective of this descriptive study was to determine generalized Lake Sturgeon movement patterns in Rainy Lake through the use of biotelemetry. Movement data obtained from tagged Lake Sturgeon were organized using a geographic information system (GIS) and used to help identify seasonal movement patterns and potential spawning locations.

Study Site

Rainy Lake, located on the Minnesota-Ontario border, consists of three main basins: the North Arm, Redgut Bay, and the South Arm, all of which are part of the Winnipeg-Nelson drainage system in the Lake Winnipeg primary watershed (Figure 1). The North Arm and Redgut Bay are both located entirely in Canada. Rainy Lake has a total surface area of 92 000 ha, a maximum depth of 49.1 m, and a mean depth of 9.9 m. Of the three main lake basins, the South Arm has the greatest surface area at 49 200 ha, with 27 300 ha in Ontario and 21 900 ha in Minnesota. The South Arm is also the deepest basin with a mean depth of 9.9 m and a maximum depth of 49.1 m. The South Arm extends for 56 km along the border of the United States

and Canada. The South Arm of Rainy Lake, along with a 40-km section of the Seine River, was the area of focus for this study.

The watershed associated with Rainy Lake encompasses over 37 500 km^2 and can be divided into two sub-basins, including a 19 270-km^2 area above the outlet of Namakan Reservoir at Kettle Falls and Squirrel Falls and a 19 320-km^2 area below Kettle Falls and Squirrel Falls that drains directly to Rainy Lake. Overflows between Namakan Reservoir and Rainy Lake also occur at Bear Portage and Gold Portage. Below Kettle Falls and Squirrel Falls there are two principal tributaries that enter Rainy Lake, the Turtle River with a mean discharge of 37 m^3/sec and the Seine River with a mean discharge of 48 m^3/sec. Smaller, ungauged tributaries into the South Arm of Rainy Lake include the Rat and Pipestone rivers, both of which may be used by Lake Sturgeon for spawning. Changes in flow initiated at the headwaters of the watershed take about 21 days to reach the outlet of Rainy Lake under normal flow conditions with the water dropping about 135 m in the 338 km between these two points (International Rainy Lake Board of Control/ International Lake of the Woods Control Board 1984*). Long-term flow records indicate that approximately 8.3 billion m^3 of water move through the Rainy Lake watershed annually (Ericson et al. 1976*).

Methods

Biotelemetry was utilized in the identification and characterization of Lake Sturgeon seasonal movement patterns and likely spawning locations in Rainy Lake. Lake Sturgeon were captured for transmitter implantation in October of 2002 (n = 13), May and June of 2003 (n = 20), and October of 2003 (n = 8) at the mouths of tributaries where they were known to concentrate (tagging locations are noted in Table 1). Large mesh multifilament gill nets with mesh sizes of 103, 114, 127, 152, and 178 mm (bar measure; i.e., distance from knot to adjacent knot) were used to capture fish. Net lengths varied from 30 to 91 m, with all nets having a height of 1.83 m. Most nets were fished for approximately 24 hours, but actual times varied among sampling crews. Captured Lake Sturgeon were measured, weighed, sex was noted if gonads were identifiable during surgery, and a pectoral fin ray section was removed for aging (Adams et al. 2006).

Lotek Wireless combined acoustic/radio transmitters (CART) were surgically implanted into 41 Lake Sturgeon (≥8 kg) throughout the duration of this study. Thus, only a single tag was implanted and used for both radio and acoustic tracking, with the radio portion of the tag allowing tracking of fish in shallow or turbulent habitats, while the ultrasonic portion of the tag was needed for tracking of Lake Sturgeon in deeper habitats (Winter 1996). Surgical implantation procedures followed guidelines set by Hart and Summerfelt (1975). A 5- to 8-cm incision was made on the ventral fish surface approximately 3 cm off the midline and approximately 3 cm from the anterior end of the pelvic girdle. A 0.5-cm exit hole for the whip antenna was started with a scalpel on the midline approximately 3 cm posterior to the incision. A curved, 12-gauge catheter needle was passed through the hole and out through the incision with care taken to not penetrate or cut the viscera. The whip antenna projecting from the CART tag was then threaded though the end of the catheter needle that was protruding through the incision with the antenna being passed out of the peritoneal cavity through the antenna hole. The CART tag was then inserted into the peritoneal cavity with minimal pressure exerted on the internal organs. Fish were placed in a holding pen following implantation, if necessary. When full equilibrium was regained, fish were placed in the water at the site of capture and monitored until they vacated the area. All fish handling and surgery followed guidelines for use of wild fishes established by Nickum et al. (2004).

Lotek CART 16-2 series tags were implanted in 33 Lake Sturgeon with the remaining eight fish receiving CART 16-1 series tags. Lotek CART 16-2 tags were 16 mm × 85 mm with a weight in air of 36 g, while Lotek CART 16-1 tags were 16 mm × 60 mm with a weight in air of 25.3 g. Implanted CART tags did not exceed 2% of the total body weight of any given fish (Gallep and Magnuson 1972; McCleave and Stred 1975; Stasko and Pincock 1977; Moser et al. 1990).

Aerial tracking of Lake Sturgeon occurred at least once per week throughout the spring spawning season and summer months when the airplane was operational. Transects were flown covering the eastern half of the South Arm, with every flight including a 40-km stretch of the Seine River that flows into Rainy Lake. Transects were chosen to maximize area covered with the least amount of flight time. The remaining portion of the South Arm was flown at least once every two flights, time and weather permitting. The North Arm of Rainy Lake was flown once in the summer of 2003 in an attempt to locate a fish that could not be located in the South Arm.

Radio tracking by boat took place on average two to three times per week depending upon weather conditions. Tracking was also dependent on time availability, with partial and full days devoted to boat tracking when possible. Locations highly used by Lake Sturgeon were sampled by boat during May and June because recognition of individual signals was difficult from the airplane.

Distributional patterns of Lake Sturgeon were summarized by month during the spawning period (May and June) and by two-month periods throughout the rest of the summer (July/August and September/October). Movement rates were calculated as the linear distance between successive fixes divided by the number of elapsed days. Lake Sturgeon home ranges were calculated using the Animal Movement extension in

FIGURE 1. Rainy Lake, Minnesota and Ontario. The line across the South Arm indicates the border between Canada and the United States.

ArcView 3.2 (Hooge et al. 1999*), with home ranges estimated by using minimum convex polygons (White and Garrett 1990). Home ranges included only water area; land masses were excluded.

Lake Sturgeon eggs were sampled during 2004 in an attempt to confirm spawning locations. Egg collectors were set weekly from 7 June through 1 July in three areas of high Lake Sturgeon use. Collectors consisted of an 18-m mainline of vinyl-coated wire cable (4.8 × 6.4 mm) with cement blocks (203 × 406 × 102 mm) attached at 3-m intervals and wrapped in furnace filter material. Floats were attached to each end of the mainline and egg collectors were set in shallow water areas of 0.3 to 4.6-m depth. Egg collectors were checked once weekly during the entire time period in which they were deployed. A sample of all egg types present on the collectors was removed and transported back to laboratory facilities to be hatched and the fry subsequently identified.

Results and Discussion

Lake Sturgeon tagging and survival

Forty-one Lake Sturgeon were implanted with CART tags during 2002 and 2003 (Table 1). Individual Lake Sturgeon were re-located between 0 and 36 times. No mortalities were positively identified. However, fish 99, implanted in October of 2003, was not located during the remainder of the study. Fish 30 was not located for 12 months after it was tagged and released, but then was subsequently located 11 times throughout the remainder of the study. Fish 106 was found at the same location, adjacent to the Seine River First Nations village on the Seine River, weekly for 11 weeks. We later learned that fish 106 may have perished in a gill net used in the Seine River First Nations subsistence fishery that had been left on the bottom of the Seine River due to entanglement with the substrate. All other fish were located at least once throughout the study.

Lake Sturgeon implanted with CART tags had a mean fork length of 1217.4 mm (range 951-1505 mm), girth of 502.4 mm (range 372-639 mm), mass of 15.35 kg (range 7.5-30 kg), and age of 25.9 (range 15-55) (Table 1). These ranges were representative of the Lake Sturgeon population in Rainy Lake at the time of this study (Adams et al. 2006).

Transmitter detection

Acoustic equipment was tested during the spring of 2003. Tags were lowered at 2-m intervals between

TABLE 1. Fish description, transmitter code, and capture location at time of tagging for Lake Sturgeon implanted with Lotek CART transmitters in Rainy Lake, 2002-2003. Ages were determined from pectoral fin ray sections. NA = not available.

2 and 20 m. The highest maximum detectable distance from the boat was 0.95 km when the CART tag was lowered to 6 m. The lowest maximum detectable distance of 0.53 km occurred at a tag depth of 18 m. The mean maximum detectable distance was 0.65 km with a standard error of 0.04. Limitations in the performance of the acoustic portion of the tags led to the discontinuation of acoustic telemetry from the study beginning during July of 2003. No fish locations were recorded with the acoustic equipment despite attempts on 10 dates between 15 May and 15 June 2003. The complexity of the bottom contours of Rainy Lake may have been the reason for the lack of reception of the directional acoustic signal.

Radio telemetry equipment was also tested. The highest maximum detectable distance from the boat was 0.47 km when the CART tag was lowered to 2 m. The lowest maximum detectable distance of 0.017 km occurred at a tag depth of 20 m. The mean maximum detectable distance was 0.21 km with a standard error of 0.05. The maximum detectable distance by airplane with the tag lowered to 8.77 m was 0.55 km with a standard error of 38.5.

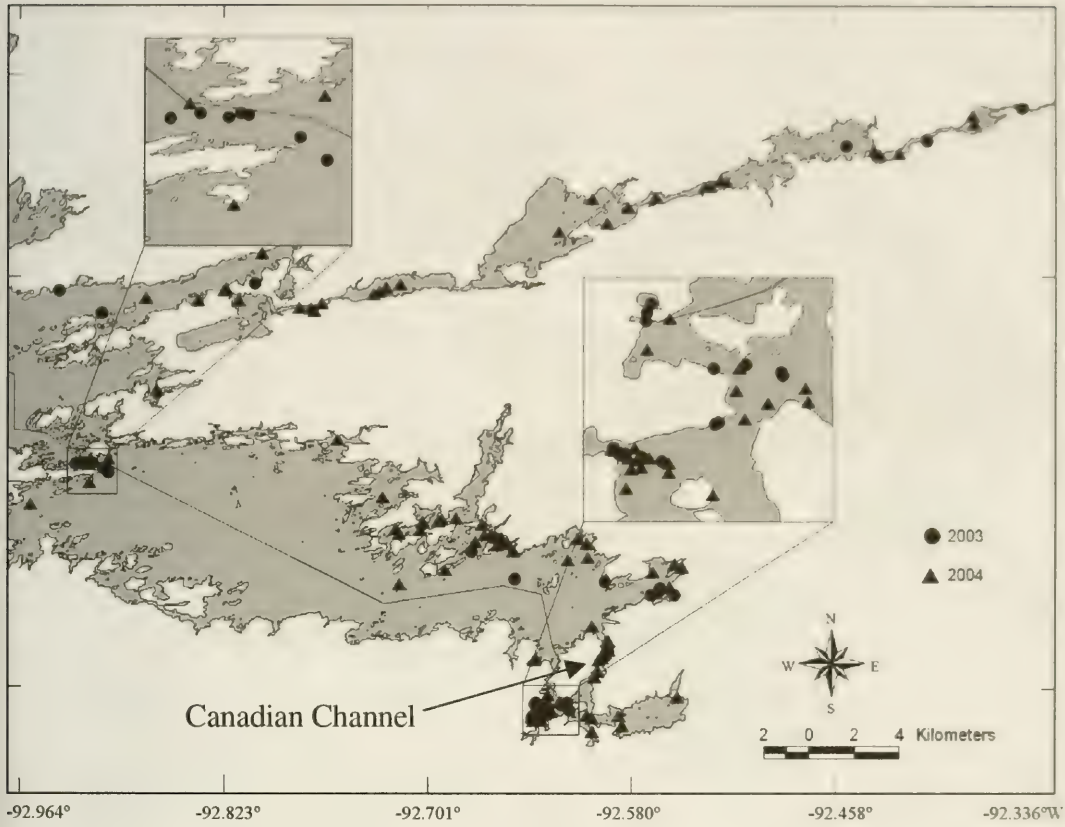

FIGURE 2. Distribution of Lake Sturgeon locations in Rainy Lake during May and June, 2003 and 2004.

Lake Sturgeon locations

The 41 implanted Lake Sturgeon were located 587 times throughout the study, with fish being tracked through September 2004. In 2003 Lake Sturgeon were located 285 times and in 2004 Lake Sturgeon were located 302 times.

Lake Sturgeon utilized Squirrel Falls/Kettle Falls and adjacent areas (Canadian Channel, Hale Bay) extensively throughout the study (37% of total locations, including both spawning and non-spawning seasons). A rock shelf below the Squirrel Falls Dam is one of the areas thought to be a spawning site for Lake Sturgeon in Rainy Lake. Egg samplers were placed below the Squirrel Falls Dam, in the Canadian Channel, and below the falls in the Pipestone River in 2004. Lake Sturgeon spawning, verified by hatching eggs and identifying larvae, was confirmed only at the Squirrel Falls Dam and occurred between 14 June and 17 June of 2004. Thus, we cannot exclude the possibility of spawning at other locations, but were able to verify spawning below the Squirrel Falls Dam. Other sites with Lake Sturgeon spawning habitat characteristics as listed by Scott and Crossman (1973) (e.g., 0.6-4.6 m depth, swift current, below falls) include the Kettle Falls Dam, Pipestone River, Rat River, and the Seine River (Crilly Dam and Highway 11 Bridge). Lake Sturgeon were located at all of these sites throughout the study, including the spawning season.

The majority of May locations (89%) for both 2003 (85%) and 2004 (90%) were associated with the current area directly below Kettle Falls, Squirrel Falls, and in the Canadian Channel (Figure 2), which suggests pre-spawning aggregations. Four of the other six May locations were associated with the Brule Narrows, also an area with consistent current.

Fewer Lake Sturgeon were located in the Kettle Falls/Squirrel Falls/Canadian Channel area as June progressed in both years (Adams 2004*). We suspect that Lake Sturgeon gradually left the spawning areas at Kettle Falls and Squirrel Falls, and dispersed primarily to the main basin east of Brule Narrows. During this month, Lake Sturgeon locations in the Seine River were spread throughout Seine Bay and 36 km upriver. The increased number of Seine River locations from 2003 to 2004 was due to the increased number of tagged Lake Sturgeon. Only four fish from the Seine River were tagged for 2003 tracking, while six additional fish were tagged for 2004 tracking.

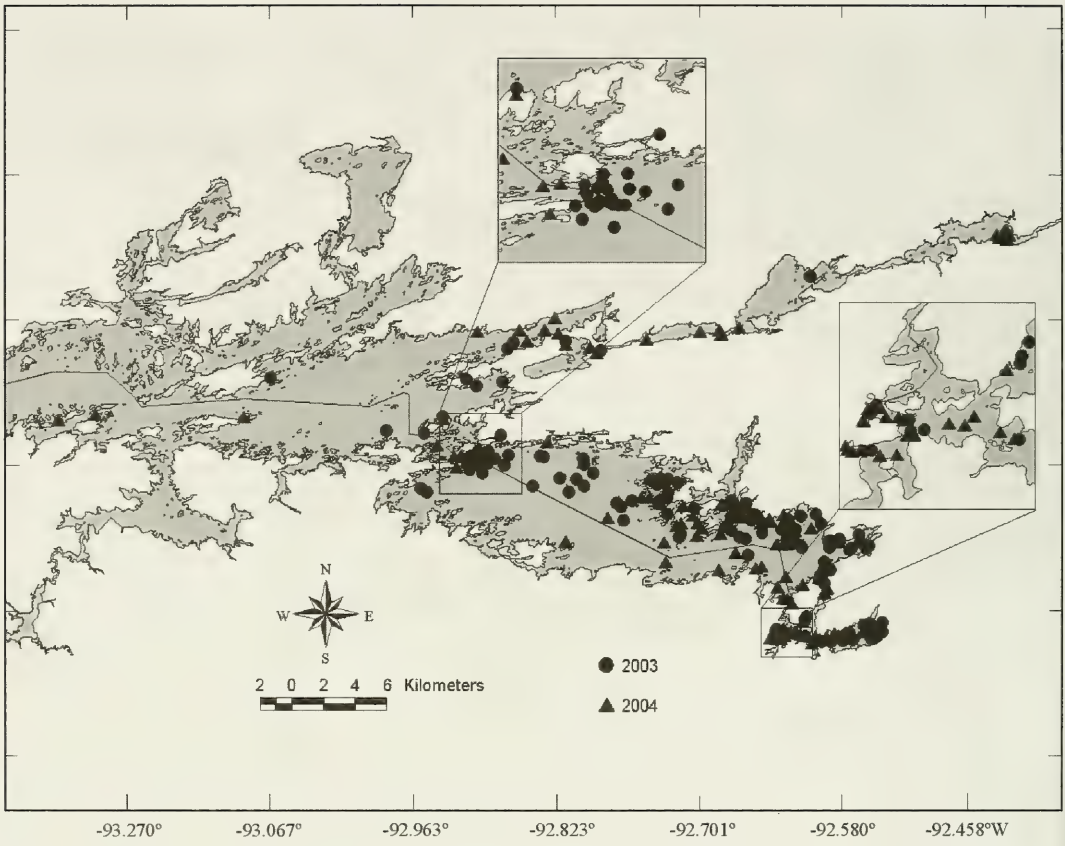

FIGURE 3. Distribution of Lake Sturgeon in Rainy Lake during July and August, 2003 and 2004.

During the July/August period, the majority of Lake Sturgeon were found from the Brule Narrows eastward and in the Seine Bay/Seine River system, with only five locations found west of the Brule Narrows (Figure 3). Some Lake Sturgeon continued to be located in the Kettle Falls/Squirrel Falls area during this period in both years (15 locations and 35 locations, respectively). Locations in the main body of the South Arm were associated with the north shore more than the south shore during this time period (96% in 2003 and 84% in 2004). There are substantial habitat differences between the two areas with the south shore consisting of a sharp drop-off into depths of over 30 m. Conversely, the north shore consists of rock reefs and depths shallower than 15 m. Either the fish were less likely to use the deeper water, or the lack of locations was due to limitations of the telemetry equipment with radio signals detected from depths no greater than 18 m.

September locations were obtained during both 2003 and 2004 with October locations obtained only in 2003. Locations during this time period were distributed throughout the South Arm (Figure 4). Locations in the Seine River were few, with zero in 2003 and two in 2004. Fish 75 was tagged in the Seine River but located in the South Arm during this time period. Lake Sturgeon were located on the south shore of the South Arm for the first time in September. One potential explanation is that Lake Sturgeon were staging at locations in the vicinity of winter habitats. Rusak and Mosindy (1997) found that Lake Sturgeon in the Lake of the Woods/Rainy River system demonstrated consistent preferences for specific areas in the main basin of Lake of the Woods during the winter; these areas were adjacent to the mouth of the Rainy River where the Lake Sturgeon would later spawn in the spring.

Lake Sturgeon movement rates

Mean movement rates of Lake Sturgeon were calculated by month for descriptive purposes (Figure 5). Movement rates increased from May to June during 2003 and 2004, with a maximum movement rate of 0.80 km/day in June of 2004 and a minimum movement rate of 0.17 km/day in May of 2003. Movement rates in five of the 10 months exceeded the mean spring

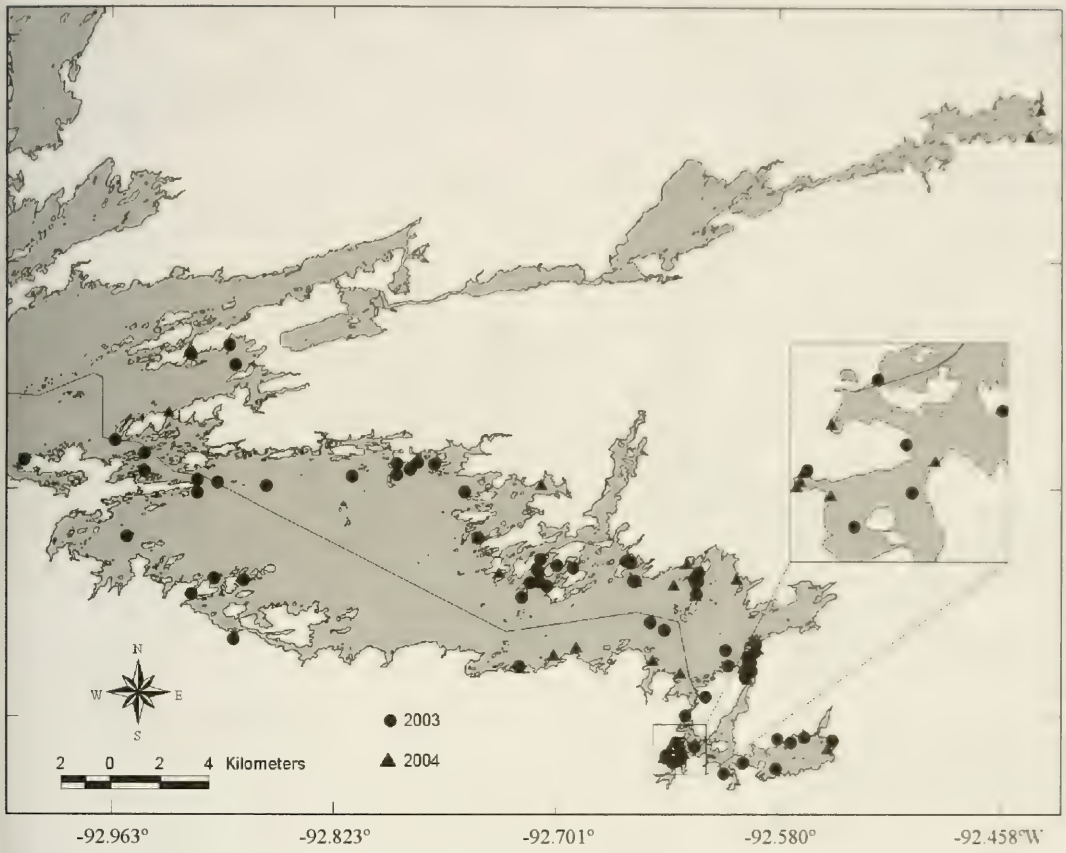

FIGURE 4. Distribution of Lake Sturgeon locations in Rainy Lake during September and October 2003 and September 2004.

movement rate of 0.50 km/day observed by Knights et al. (2002) for Lake Sturgeon in the upper Mississippi River system. Lake Sturgeon in Rainy Lake likely were dispersing into the lake away from spawning sites during the post-spawn period in June. However, movement rate patterns were dissimilar for the same months between years. Further research thus will be needed to ascertain seasonal movement patterns and explanations for those patterns.

Movement of fish between the Seine River and the main body of the South Arm did occur but was minimal throughout the study. Rusak and Mosindy (1997) found that in the Lake of the Woods/Rainy River system, there was a separation in the population based primarily on winter habitat use. "River" fish spawned in the Rainy River and remained there throughout the winter months. "Lake" fish spawned in the Rainy River but moved into the main basin of Lake of the Woods during the winter months. If a similar dichotomy exists in the Rainy Lake/Seine River population, there may be greater movement of Lake Sturgeon between these two areas during the time period in which we did not attempt to locate fish (i.e., late fall and winter). Thus, Lake Sturgeon may move from Rainy Lake into the Seine River during this time period, but further investigation will be needed.

Movement patterns varied for individual Lake Sturgeon in Rainy Lake. Some fish did not exhibit discernable movement patterns, such as fish 21, which was located throughout the east end of the South Arm from Stokes Bay to the Brule Narrows and also in Seine Bay and at the mouth of Seine Bay (Figure 6). Locations in 2003 began in the east and moved west with the last location east of the Brule Narrows. The first locations in 2004 were in the Seine Bay/Seine River area with the remainder of locations further east. One factor contributing to the differential patterns between years may be the spawning interval exhibited by Lake Sturgeon, which ranges between 1 and 3 years for males and 4 and 6 years for females (Magnin 1966).

Telemetry results from Rainy Lake suggest that some Lake Sturgeon remained in the same area for

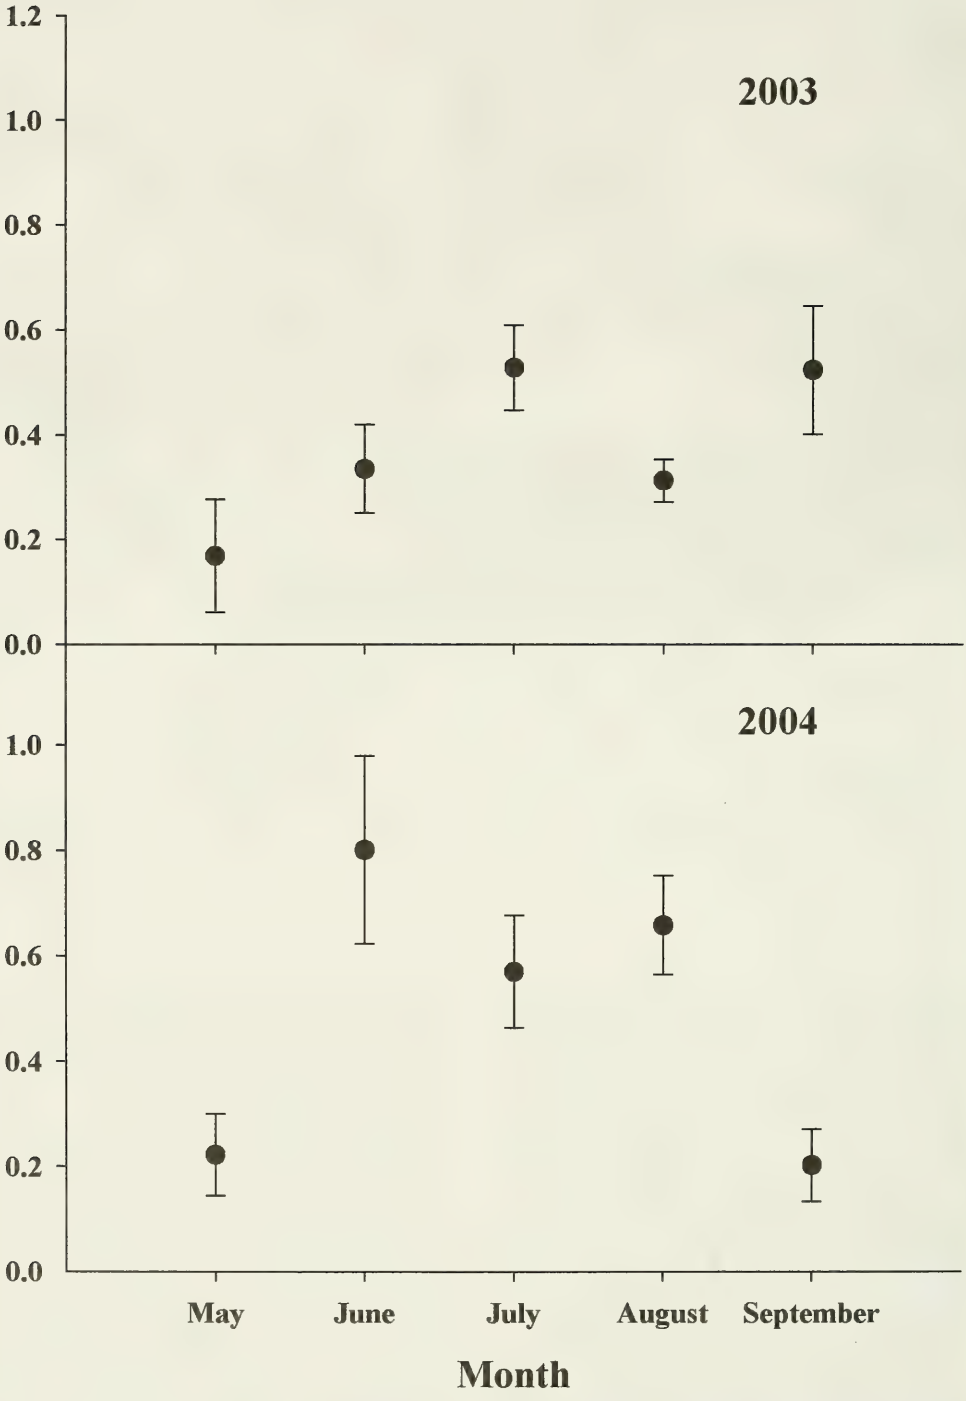

FIGURE 5. Mean monthly movement rate (± standard error) of Lake Sturgeon in Rainy Lake during 2003 and 2004.

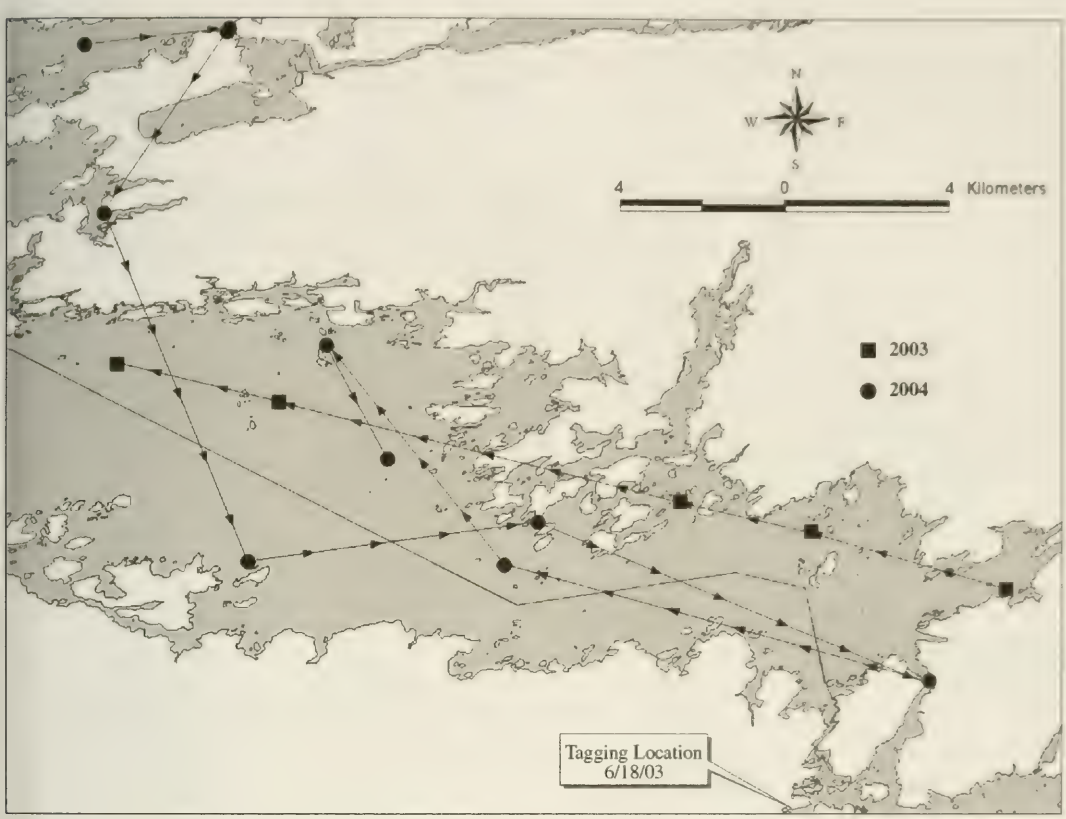

FIGURE 6. Distribution of locations for Lake Sturgeon number 21 in Rainy Lake, 2003 and 2004.

extended periods. For example, fish 15 was tagged at the Squirrel Falls Dam on 28 May 2003 and was next located in the Brule Narrows area (Figure 7). Subsequent locations were all in the area of the Brule Narrows until 26 August 2003. The next locations were in the Squirrel Falls Dam area beginning on 28 September 2003. The fish was then located in the Squirrel Falls Dam area on 18 May 2004 and was not located in the Brule Narrows area until 30 June 2004.

Lake Sturgeon home ranges

Home ranges for Lake Sturgeon in Rainy Lake varied substantially, with a maximum home range size of 14 844 ha, a minimum size (excluding fish 106, possible mortality) of 84 ha, and a mean home range size of 4 625 ha (standard error = 642). Lyons and Kempinger (1992*) reported that most Lake Sturgeon in the Lake Winnebago system had consistent movement patterns, while others demonstrated variable movement patterns and apparently did not establish home ranges. They also found that Lake Sturgeon in Lake Winnebago did not remain in any particular location for long periods of time.

Conclusions

This research should provide biologists from multiple agencies insight into general movement patterns of Lake Sturgeon inhabiting Rainy Lake. Telemetry data indicated high utilization of the Squirrel Falls area, with 37% of total locations occurring at that area. Squirrel Falls was the only site at which spawning was confirmed by collection of Lake Sturgeon eggs, although other aggregations in areas associated with Kettle Falls, the Pipestone River, and the Rat River also could indicate spawning activity. Movement of Lake Sturgeon between the Seine River and the South Arm of Rainy Lake indicates the likelihood of one integrated population on the east end of the South Arm. The lack of locations in the Seine River during the months of September and October might result from Lake Sturgeon moving into deeper water areas of the Seine River and out of the range of telemetry gear or simply moving back into the South Arm. Further research will be needed to determine the winter range of Lake Sturgeon in Rainy Lake. The Lake Sturgeon has historically been a resource of both cultural and economic importance to the Rainy Lake area. Due to

TABLE 2. Home ranges and mean movement rates (SD) by year for Lake Sturgeon in Rainy Lake. Missing values (dots) indicate that a fish was located zero or one times that year and thus movement could not be calculated.

Northern Range Expansion and Invasion by the Common Carp, *Cyprinus carpio*, of the Churchill River System in Manitoba

PASCAL H. J. BADIOU[1] and L. GORDON GOLDSBOROUGH[1,2]

Badiou, Pascal H.J., and L. Gordon Goldsborough. 2006. Northern range expansion and invasion by the Common Carp, *Cyprinus carpio*, of the Churchill River system in Manitoba. Canadian Field-Naturalist 120(1): 83–86.

Recent fisheries data from northern Manitoba indicates that the Common Carp (*Cyprinus carpio*) has extended the northern limit of its range. Additionally, it also appears that carp have invaded and established viable populations in the Manitoba portion of the Churchill River. Habitat degradation and altered flow regimes as result of hydroelectric development in northern Manitoba may have facilitated the expansion of carp in the region.

Key Words: Common Carp, *Cyprinus carpio*, exotic species, range expansion, invasion, habitat disturbance, Manitoba

The Common Carp (*Cyprinus carpio*) was introduced intentionally to Manitoba, Canada, when fish from Minnesota were stocked in the Assiniboine River watershed southeast of Brandon in 1886 (Stewart and Watkinson 2004). These early attempts at introduction failed, and carp only became established after populations from the northern U.S. entered the province through the Red River (Atton 1959). In fact, the Common Carp was largely unknown in Manitoba until 1938, when it was positively identified in the Red River near Rockport (Hinks 1943). Today, the Common Carp is found throughout most of the southern and central regions of the province, but particularly in the Red and Assiniboine rivers, and lakes Manitoba, Winnipeg, and Winnipegosis. Common Carp do not appear to have extended into the eastern portion of the province, likely due to the fact that they cannot easily migrate upstream in this region because of the many obstructions they would encounter (i.e., Beaver dams). Additionally, lakes in this portion of the province are characterized by rocky substrates and clear deep waters typical of the Precambrian Shield and do not provide suitable habitat for viable populations of the Common Carp.

Benthivorous fish such as the Common Carp can have profound effects in aquatic ecosystems by increasing turbidity through sediment resuspension while foraging and spawning (Breukelaar et al. 1994; Zambrano et al. 2001). Carp are known to uproot submerged macrophytes during spawning and accidentally consume them while foraging for benthic invertebrates (Wolterman 1990; Roberts et al. 1995; Lougheed et al. 1998; Zambrano and Hinojosa 1999). Sediment resuspension and excretion by carp can increase water column nutrient concentrations, thereby causing phytoplankton to flourish (Lamarra 1975; Breukelaar et al. 1994; King et al. 1997). A shading effect results from these blooms, further suppressing submerged macrophytes and creating an ecological feedback mechanism that perpetuates the turbid state (Scheffer 1998). Carp physically disturb the sediment-water interface and the algae associated with sediment. These algae play a major role in the stabilization of the bottom sediments (Taylor et al. 1998) and the regulation of nutrient fluxes across the sediment-water interface (Goldsborough and Robinson 1985; Carlton and Wetzel 1988; Woodruff et al. 1999). It is thought that many of the once clear, shallow lakes and wetlands in southern Manitoba have switched to the turbid state due to the loss of submerged macrophyte cover which, in turn, was caused by the proliferation of Common Carp (Badiou 2005).

Before 1940, carp were found only in the waters of the Red River (Figure 1a). After invading the province from the south, the Common Carp spread quickly throughout the Red and Assiniboine River watersheds prior to the 1950s and established themselves in the south basins of lakes Winnipeg and Manitoba (Figure 1b). However, the greatest range expansion occurred between 1950 and 1970 when carp were easily able to access the northern and western portions of the province after successfully invading Lake Winnipeg, Lake Manitoba, and Lake Winnipegosis, the largest lakes in the province (Figure 1c). Swain (1979) indicated that by 1976 the Common Carp was found in most large lakes and virtually all major rivers in Manitoba, with the exception of the Churchill River system.

A specimen collected from Split Lake (Figure 1d) in 1963 was considered to be the most northerly record for the distribution of carp in the world (McCrimmon 1968). These original reports stated that carp caught from Split Lake appeared emaciated and unhealthy. According to Atton (1959), cold summer temperatures prevented the carp from invading the Churchill River system. However, as shown in Figure 1d, the Common Carp has migrated northward through the Nelson River

system and, in the last decade, has become established in the Churchill River system according to carp production data spanning the period from 1970 to 2004.

On the Nelson River system, carp have become established in Split Lake where commercial catches (3–74 kg per year) have been reported starting in 1996. Fish monitoring studies for the Limestone Generating Station (C. Barth, personal communication) and the proposed Gull Generating Station (D. J. Pisiak, unpublished data) documented Common Carp in Stephens Lake and in the forebay of the Limestone Generating Station (Figure 1d). Furthermore, during the course of fish studies for the proposed Conawapa Generating Station, a large, approximately 4 kg, Common Carp was caught in a backwater area near the lower Limestone Rapids (P. Nelson, personal communication). This is the first report of Common Carp downstream of the Limestone Generating Station and the most northerly location documented for the Nelson River.

More important than the northward expansion of carp on the Nelson River system is the invasion of the Churchill River system in the last decade. Recent fisheries records for northern Manitoba provided by the Freshwater Fish Marketing Corporation indicate that the Common Carp is now established in and around the Churchill River system with commercial catches reported from Britton, Guthrie, Highrock, Loon, Sisipuk, and Southern Indian lakes (Figure 1d). Commercial catches in these lakes were much higher (range 8–1184 kg per year) relative to those from Split Lake on the Nelson River system. Carp were likely introduced into the Churchill River system from the Saskatchewan River system, either by fishers using them as bait or by birds that may have inoculated carp eggs from one system into the other. A thorough search of the primary literature and government documents revealed that Common Carp have not been reported in the Saskatchewan portion of the Churchill River. The fact that carp have not been reported in the Churchill River in Saskatchewan indicates that the transfer of the Common Carp between the Saskatchewan River and Churchill River systems must have occurred within the province of Manitoba in the vast wetland area that occurs between these two watersheds along the Manitoba/Saskatchewan border.

Based on the fact that carp were found in Split Lake as early as 1963, it is not surprising that they have continued to migrate northward through the Nelson River system. However, given the poor condition of carp in Split Lake in 1963, a change must have occurred, which has allowed them to persist in this system. The two basic habitat requirements necessary to sustain carp populations are: (1) a shallow marsh environment with abundant aquatic vegetation for spawning and, (2) an area of deep water where carp can overwinter (McCrimmon 1968). We hypothesize that the construction of the Kettle Generating Station in 1974 at the outlet of Stephens Lake on the Nelson River provided the necessary habitat requirements to allow the establishment and sustain viable populations of Common Carp in Split Lake and Stephens Lake. Construction of this generating station increased the size of Stephens Lake by 242 km^2 and resulted in the flooding of 192 km^2 of land (Environment Canada / Fisheries and Oceans 1992a). This created an extensive area of shallow marsh-like habitat where carp could spawn in the summer. This was the case in Ontario where Swee and McCrimmon (1966) reported that Lake St. Lawrence near Cornwall, formed as the result of flooding during hydroelectric development on the St. Lawrence River, provided ideal spawning habitat for the Common Carp. However, it was also noted that fluctuations in lake level associated with hydroelectric activities caused many of the eggs attached to vegetation to be exposed and destroyed. More importantly, the construction of the Kettle Generating Station, with a forebay head of 30 meters (Environment Canada / Fisheries and Oceans 1992a), created a deep basin with warmer profundal zone waters to which carp can escape during cold winter months.

The completion of the Churchill River Diversion in 1976 raised the water level in Southern Indian Lake by approximately 3 m and flooded 187 km^2 of surrounding land (Environment Canada / Fisheries and Oceans 1992a). Like the flooding experienced on Stephens Lake after the construction of the Kettle Generating Station, flooding on Southern Indian Lake would have also provided ideal spawning habitat for carp. The extensive flooding on Southern Indian Lake increased shoreline erosion and drastically increased suspended sediment concentrations in the lake from 5 $mg{\cdot}L^{-1}$, pre-impoundment, to 30-50 $mg{\cdot}L^{-1}$, post-impoundment (Environment Canada / Fisheries and Oceans 1992b). This anthropogenic increase in suspended sediments would have conferred a competitive advantage on carp which can feed more efficiently in highly turbid waters due to their superior olfactory senses, relative to sight-feeders (Panek 1987).

Water flows on the Churchill and Nelson river systems have been altered dramatically as a result of the Churchill River Diversion, which has diverted 80% of the flow from the Churchill River at Southern Indian Lake into the Nelson River system. Carp are found in large, slow-moving rivers as well as fast flowing streams (Panek 1987). Due to the ability of carp to inhabit waters of varying flow, the increased flow on the Nelson and decreased flow on the Churchill, as well as the increased variability in flows in both systems as a result of hydroelectric development, would also have conferred an advantage on the Common Carp relative to native fish that may be less tolerant of variations in flow regime.

Overall, it is not surprising that Common Carp are invading northern Manitoba in step with hydroelectric development, as many authors have demonstrated the link between anthropogenic habitat alteration and invadability of ecosystems (Moyle and Light 1996; Keith and James 1999; Byers 2002). Keith and James (1999) showed a positive correlation between the num-

FIGURE 1. Range expansion of the Common Carp (*Cyprinus carpio*) in Manitoba (A) prior to 1940, (B) prior to 1950, (C) prior to 1970, and (D) prior to 2000. Carp distributions prior to 1970 were estimated based on date of first occurrences reported in Swain (1979), while the range expansion between 1970 and 2000 was estimated from carp production data provided by Manitoba Conservation and the Freshwater Water Fish Marketing Corporation for the period from 1970 to 2000. Numbers in D indicate locations discussed in the text: (1) Split Lake, (2) Stephens Lake, (3) Limestone Generating Station, (4) Britton Lake, (5) Sisipuk Lake, (6) Guthrie Lake, (7) Highrock Lake, (8) Southern Indian Lake, (9) Loon Lake, (10) Churchill River Estuary, and (11) Nelson River Estuary.

ber of reservoirs and the number of introduced species in North American drainages. Given that the Common Carp has already been reported in subarctic regions (Lukin 1999) and is tolerant of a wide range of salinity levels (Lam and Sharma 1985) it is a matter of time before the populations of carp established on the Nelson and Churchill river systems reach the Churchill River and Nelson river estuaries.

Acknowledgments

We thank Ellen Smith of the Freshwater Fish Marketing Corporation for providing us with carp production data from Manitoba lakes. We also thank Patrick Nelson, Paul Graveline and Cam Barth of North/South Consultants Inc., in Winnipeg for helpful comments. This is publication number 311 from the Delta Marsh Field Station (University of Manitoba).

Diversity and Range of Amphibians of the Yukon Territory

Brian G. Slough[1] and R. Lee Mennell[2]

[1] 35 Cronkhite Road, Whitehorse, Yukon Territory Y1A 5S9 Canada
[2] P.O. Box 10002, Whitehorse, Yukon Territory Y1A 7A1 Canada

Slough, Brian G., and R. Lee Mennell. 2006. Diversity and range of amphibians of the Yukon Territory. Canadian Field-Naturalist 120(1): 87-92.

Four amphibian species occur in the Yukon: Western Toad (*Bufo boreas*; first verified record in 1961), the Boreal Chorus Frog (*Pseudacris maculata*, first record in 1995), the Columbia Spotted Frog (*Rana luteiventris*, first record in 1993), and the Wood Frog (*Rana sylvatica*; first record in 1933). The Western Toad is restricted to the Liard Basin in five geographically separated areas. Breeding sites have been located on the lower Coal River and vicinity. The Boreal Chorus Frog has been documented from a small area of the lower La Biche River valley near the Yukon-British Columbia-Northwest Territories border. The Columbia Spotted Frog occurs in two widely separated areas, at Bennett Lake in the southwest and in the Liard Basin in the southeast. The Wood Frog is widespread below treeline. Limited survey efforts continue to hinder our knowledge of amphibian distribution.

Key Words: *Bufo boreas*, Western Toad, *Pseudacris maculata*, Boreal Chorus Frog, *Rana luteiventris*, Columbia Spotted Frog, *Rana sylvatica*, Wood Frog, amphibian, Yukon, distribution.

Biological surveys began in the interior of the Yukon Territory in 1899 (Osgood and Bishop 1900); however, these were often directed at mammals and birds, and did not report amphibian observations. The earliest known amphibian records for the region are from Atlin (Slevin 1928; Western Toad and Wood Frog) and Bennett Lake, British Columbia (Logier 1932; Columbia Spotted Frog, formerly Western Spotted Frog). The first published report of amphibians in the Yukon was by Loomis and Jones (1953), who reported a Wood Frog collected at Dezadeash Lake in 1948 by the University of Kansas Museum of Natural History. Museum collections from the Canadian Museum of Nature (CMN) and the American Museum of Natural History (AMNH) date to 1933 and 1936, respectively. Logier and Toner (1961) report only the single locality record of Loomis and Jones (1953). Using an expanded database, including museum specimens and inferences from locality records in Alaska, the Northwest Territories and British Columbia, Martof (1970) shows an approximate range for the Wood Frog; although a large area with no data existed in the eastern and northern Yukon. The amphibian range maps in Stebbins (2003) were modified with information provided by BGS.

The Western Toad (*Bufo boreas*) was first observed in 1961 in the southeast Yukon (Cook 1977). The Columbia Spotted Frog was first observed in 1993 (Mennell 1997) in the southwest Yukon. There are no published records of the Boreal Chorus Frog or other species for the Yukon. All species of amphibians have been underrepresented in records due to the remoteness of breeding sites and lack of directed surveys. Several amphibian surveys and expert observations have been made since 1993 by the authors and others, and the data have remained unpublished. We typically used visual encounter surveys and dipnetting of terrestrial, semi-terrestrial (wetland) and aquatic habitats (Thoms et al. 1997). We review unpublished data, unpublished reports and museum collections to present an update on the amphibian species of the Yukon and their ranges. Anecdotal information on phenology and habitats is provided. Scientific and common names follow Collins and Taggart (2002).

Species Accounts

Western Toad (*Bufo boreas*)

Western Toads occur from south-coastal Alaska, through western Canada and the western United States to Baja California. Cook (1977) reported two museum specimens of the Western Toad from the Yukon. The Whitehorse specimen, collected in 1948, was verified in 1997 by F. Cook, who also verified the label in 2003 as collected by William Mason July 1-10. Mason was an entomologist and the date notation suggests a specimen taken in a pan or similar trap set for that period and contents preserved on the last date (F. Cook, personal communication). This specimen is here considered to be either an extra-limital stray or erroneously labelled, since the nearest confirmed breeding records of Western Toads are 100 km to the south in British Columbia on Bennett Lake (Slough 2004*; 17 km from the British Columbia-Yukon border) and on Tagish Lake (Mennell and Slough 1998*; 40 km from the border). A single adult was found in non-breeding habitat on Tagish Lake 9 km from the border (Mennell and Slough 1998*). All other records are from the Liard Basin in the southeast Yukon, where the Western Toad is now known from at least 11 populations in five geographically separated areas (Figure 1). These are summarized from west to east.

Two adult Western Toads were observed near a geothermal spring on the Meister River (60°17'N, 130°07'W) in 1988 (D. Mossop, personal communi-

cation). RLM searched this area in 2004 but did not observe Western Toads. A single adult was observed near Upper Liard (60°05'N, 128°58'W) in 2004 (C. Eckert, personal communication; verified from photographs).

At least six breeding populations of Western Toads occur in close proximity (within 16 km) on the lower Coal River and wetlands to the west. The most visited population and breeding site is the Coal River Springs (60°09'N, 127°26'W). G. Scotter collected two specimens in 1977 (CMN 17798-1 and -2), and at least six Western Toad records of adults and metamorphs were documented between 1982 and 2004 (B. Slough and L. Mennell, unpublished data; Slough 2005a*). Two breeding sites exist in spring marshes below the upper and lower springs. The temperature of the main source pool is 11°C, likely maintaining frost-free hibernating sites nearby. Other breeding sites occur in riparian floodplain backwater channels and ponds above the springs (60°11'N, 127°29'W), below the springs on an island in the Coal River (60°07'N, 127°24'W), and further downstream on the Coal River in a bedrock pool [60°08'N, 127°14'W] (J. Staniforth and J. Meikle, personal communication; L. Mennell, unpublished data; Slough 2005a*). Juvenile toads have also been observed in the chain of lakes southwest of the springs (60°14'N, 127°29'W) [B. Slough, unpublished data; Slough 2005a*] and in a tributary of the lakes (60°06'N, 127°32'W) [Slough 2005b*], suggesting the presence of breeding populations.

Cook (1977) reported a specimen collected in 1961 from North Toobally Lake (60°20'N, 126°15'W). An adult Western Toad was observed 23 km to the south near South Toobally Lake (60°08'N, 126°19'W) in 1996 (C. Eckert, H. Grunberg, P. Sinclair, personal communication; verified from photograph). A single adult Western Toad was observed on the lower Beaver River [60°02'N, 124°32'W] in 1997 (B. Bennett, V. Loewen, J. Staniforth, personal communication; verified from photograph). All of the Western Toad localities are low elevation sites with early deep snow accumulation. The snow cover likely prevents deep frost penetration and permits safe hibernation, as speculated by Cook (1977).

Western Toad breeding sites are predominantly shallow, silty areas on ponds, lakes and rivers. Adults are often encountered far from water in forests or meadows. Breeding dates in the Yukon are unknown; however, populations in northwestern British Columbia breed in late May (B. Slough and L. Mennell, unpublished data). A population in the Atlin Warm Springs, 20 km south of Atlin, breeds in late February-early March. Tadpoles have been observed on the Coal River in July, and tadpoles and metamorphs were observed there on 10 August 2004.

BOREAL CHORUS FROG *Pseudacris maculata*

While *Pseudacris maculata* is currently considered a distinct species following Platz (1989), it was formerly called *P. triseriata maculata* (and earlier *Pseudacris triseriata septentrionalis*). Recent phylogeographic studies of North American chorus frogs have shown that range limits and taxonomy of the *triseriata* complex may need revision (Moriarty and Cannatella 2004). The Boreal Chorus Frog ranges across much of central North America east of the continental divide, from the Northwest Territories to southern James Bay and south to Arizona and New Mexico. We present the first records of the Boreal Chorus Frog from the Yukon. Boreal Chorus Frog calls were identified at five natural wetlands and roadside/airstrip ditches along a 10 km section of road and airstrip in the lower La Biche River valley in the southeast Yukon (60°03'N 123°58'W to 60°08'N 124°03'W) between 8 and 17 June in 1995, 1997 and 1999 (Figure 1) [B. Bennett, C. Eckert, V. Loewen, P. Sinclair, J. Staniforth, personal communication; B. Slough, unpublished data]. BGS also identified Boreal Chorus Frog tadpoles there on 10 June 1999. Extensive surveys by the authors in southeastern Yukon in 2004 did not yield any further observations of the species. Matsuda et al. (2006) show the species 160 km to the southeast at Fort Nelson, British Columbia, and it occurs 125 km northeast at the junction of the South Nahanni and Liard rivers (Fournier 1998*).

COLUMBIA SPOTTED FROG *(Rana luteiventris)*

The Columbia Spotted Frog occurs between the Rocky Mountains and Coast Ranges from the Yukon to Utah and Nevada in the south. Mennell (1997) located two populations of Columbia Spotted Frogs adjacent to the West Arm of Bennett Lake in 1993, in a pond (60°05'N 135°01'W) and a beaver pond on a creek (60°01'N 135°12'W) [Figure 1]. Slough (2002) obtained single voucher specimens and preserved toe-tips (for phylogeographic studies, n=10 and 11, respectively) from the two ponds in 2001 (Slough et al. 2002*). A third population was found in a beaver pond in the same area (Slough 2002) [60°03'N 134°58'W] where a voucher specimen and six toe-tips were obtained; specimens are held at the Redpath Museum, McGill University [RM 3382, 3379 and 3381 for the three populations, respectively]. Additional Columbia Spotted Frog adults (n=7 in 4 sites) were observed within 2.5 km of Site 2 in apparent non-breeding habitats (i.e., early life-stages not observed) along the Partridge River to Bennett Lake (R. McClure, personal communication, verified from photograph; B. Slough and L. Mennell, unpublished data). These three breeding populations are the most northerly of a series of populations that extends into northwestern British Columbia (Matsuda et al. 2006, Mennell 1997; Mennell and Slough 1998*; Slough et al. 2002*).

In 2003, two adult Columbia Spotted Frogs were observed in Irons Creek Lake in the southeastern Yukon (60°00'N 127°05'W; P. Hovingh, personal communication to Yukon Fish and Wildlife Branch) (Figure 1). Several adults, juveniles and one egg mass were observed in 2004 and 2005 (Slough 2005b*). The long-

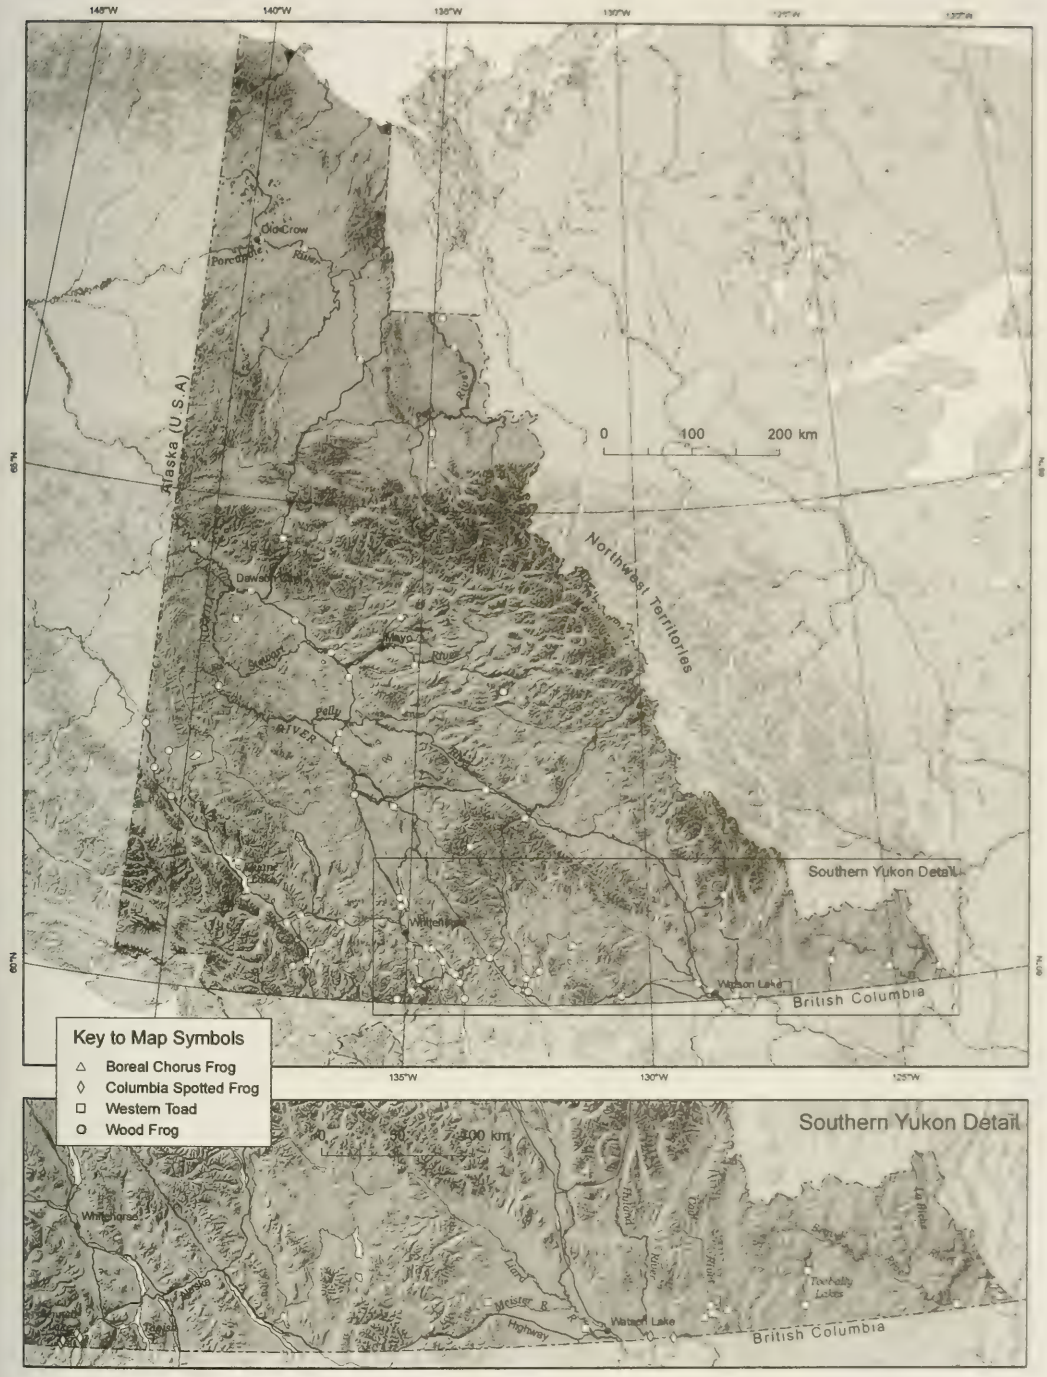

FIGURE 2. Distribution of amphibians in the Yukon. Refer to text for data sources. Shaded areas are mountain ranges.

term prospects of this population are unknown as this small lake has regularly been stocked with Rainbow Trout (*Oncorhynchus mykiss*) since 1990, with the latest stocking occurring in 2003 (D. Toews, personal communication). Rainbow trout are known to prey on Columbia Spotted Frog tadpoles and juveniles, which overwinter in lakes (Pilliod and Peterson 2000). Furthermore the heavily forested shoreline habitat is atypical for Columbia Spotted Frogs (Ovaska 1999*). The species has been observed only on human-altered shoreline which has been cleared of trees and graded into Irons Creek Lake, creating shallows. In 2004, RLM observed an adult Columbia Spotted Frog 15 km west of this site on an ox-bow channel of the Hyland River (60°01'N 127°12'W).

The Columbia Spotted Frog localities in the Liard Basin and Coast Mountain Cordillera are in areas with early deep snow accumulation which likely prevents thick ice formation and permits safe aquatic hibernation.

Columbia Spotted Frogs were noticeably abundant in and around pond outlets, where they were invariably perched at the waters edge. Breeding and transformation dates in the Yukon are unknown; however populations in nearby northwestern British Columbia have been observed extensively (Mennell 1998*; B. Slough, unpublished data). Breeding takes place on a single warm day from 18-22 May (six years of observations) in traditional shallow basins along the margins of ponds. Some of the ponds may be partially ice-covered with melting snow surrounding the ponds. They breed communally with up to 30 individuals congregating in a few square metres. Males begin calling above water over a larger area and finally call underwater as the aggregation consolidates and begins amplexis, leaving a mass of egg clutches unattached in shallow water. Breeding sites are occasionally compromised by falling water levels, leaving egg masses landlocked and stranded. Tadpoles are free-swimming in 14-16 days and metamorphs appear on pond edges throughout August (Mennell 1998*). Metamorphs have also been observed in late May, and tadpoles have been observed in mid-September at higher elevation ponds, suggesting that some tadpoles overwinter.

WOOD FROG *(Rana sylvatica)*

The Wood Frog ranges from northern Alaska and the Yukon through most of Canada below treeline east to the Atlantic and south to the Appalachian Mountains. Disjunct populations occur in several states south of this range. Numerous collections and observations reveal that Wood Frogs are common and abundant in wetlands across the Yukon below the arctic and alpine treeline (B. Slough, unpublished data) [Figure 1]. The most northerly location is Ney Khwi Vun ("Frogs in the Lake"), on the Old Crow Flats (68°01'N 140°05'W; Gray and Alt 2000*). Museum collections exist in the University of Kansas Museum of Natural History (n = 1), the American Museum of Natural History (n = 16), the Canadian Museum of Nature (n=56) and the Auke Bay Laboratory, Alaska Fisheries Science Center (Hodge 1976; n = 2). One of the museum specimens from mouth of Coal Creek (AMNH 44751) was originally misidentified as *Pseudacris septentrionalis* (now *P. maculata*) until verification as a Wood Frog in 1995 by L. S. Ford Curatorial Associate, AMNH (F. Cook, personal communication to P. Milligan). In July 2000, BGS obtained Wood Frog samples for phylogeographic studies (J. Irwin and J. Lee-Yaw, unpublished data); eight juveniles from Nogold Creek, west of Mayo (63°26'N 135°06'W), and 10 juveniles from south of Whitehorse (60°35'N 134°58'W). The CMN also has tissue from 11 adults and 25 juveniles from "Paddy's Pond", Whitehorse, July and August 1992 by Gerry Whitley.

The Wood Frog specimens and observations (Figure 1) document an extensive range for the species in the Yukon. Most observations are from road and river access corridors, and gaps in the range exist in inaccessible areas. We believe that the species occupies suitable habitats below treeline within these gaps. Furthermore, the distribution is continuous in areas of extensive wetlands such as the Whitehorse area, where only a small sample of locations was plotted. Yukon Wood Frogs were assigned to the Alaskan phenotype by Martof and Humphries (1959). While we have no data on most visible characters used to differentiate the types, there is a north-south gradient in the frequency occurrence of the mid-dorsal stripe, from approximately 100% in the north and central Yukon to 50% or less in the south.

Wood frogs breed in the Yukon as soon as shorelines become ice-free in late April-early May. They breed over a period of up to two weeks, they are frequently solitary breeders, and they do not necessarily use traditional breeding sites, but use any site with shallow water and sparse emergent grass or sedge vegetation. Egg masses are attached singly to grass or sedge stalks. Metamorphs move onto land throughout July. The most common Wood Frog breeding habitats are shallow, permanent and fishless ponds.

Neighbouring Species

Three species of salamanders occur near the southwestern Yukon, but have yet to be recorded there. The Long-toed Salamander (*Ambystoma macrodactylum*) ranges as far north as the Taku River (Hodge 1976; P. Milligan, personal communication; Mennell and Slough 1998*) and upstream to the junction of the Nakina and Sloko rivers (K. Heinemeyer, personal communication), 110 km from the British Columbia-Yukon border (observation not shown by Matsuda et al. 2006). The Northwestern Salamander (*Ambystoma gracile*) and Roughskin Newt (*Taricha granulosa*) occur in Southeast Alaska (MacDonald 2003), but they occupy Pacific coastal habitats not present in the Yukon.

Future Surveys

Dedicated amphibian surveys and expert observations have greatly increased our knowledge of the species and their ranges in the Yukon. We presented significant new observations of Western Toads, Columbia Spotted Frogs and Wood Frogs for the Yukon, and the first records of Boreal Chorus Frogs. Continued efforts should identify additional populations, their degree of isolation and habitat requirements; all necessary for conservation planning. The ranges of the Western Toad, Columbia Spotted Frog and Boreal Chorus Frog in the Yukon imply data deficiencies for these species in northern British Columbia. The Columbia Spotted Frog is common on Atlin Lake, south of Atlin (Slough et al. 2002*; not shown by Matsuda et al. 2006).

Acknowledgments

Funding to BGS and RLM for field surveys was provided by NatureServe Yukon, Yukon Department of Environment; and by Northern Research Endowment Grants from the Northern Research Institute, Yukon College. Canadian Parks and Wilderness Society-Yukon Chapter kindly supported BGS on several wilderness trips. We are grateful to the many individuals who reported amphibian sightings. Significant Wood Frog sightings were reported by D. Mossop, J. Meikle, L. Karnis, M. Gill, R. Lamb and G. Whitley. E. Wind and T. Jung reviewed earlier versions of the manuscript. G. Perrier of Dragonfly Maps provided digital cartographic design of the distribution map. We thank P. Milligan for his work as the founding Yukon DAPCAN coordinator.

Simard, Peter, Jennifer L. Lawlor, and Shannon Gowans. 2006. Temporal variability of cetaceans near Halifax, Nova Scotia. Canadian Field-Naturalist 120(1): 93–99.

Annual and seasonal trends in sightings of coastal cetaceans near Halifax, Nova Scotia, were studied using observations from whale watching and dedicated research vessels from late spring to early fall of 1996 to 2005. Four species of cetaceans routinely used the area during the summer: White-beaked and Atlantic White-sided dolphins (*Lagenorhynchus albirostris* and *L. acutus*), Harbour Porpoises (*Phocoena phocoena*), and Minke Whales (*Balaenoptera acutorostrata*). The dolphin species were temporally separated, with White-beaked Dolphins being common earlier in the summer than White-sided Dolphins. White-sided Dolphins were unusually abundant in 1997, and were found in larger groups (mean = 46.5 ± 46.19 sd) than White-beaked Dolphins (mean = 9.1 ± 5.19 SD). The area also appears to be an important habitat for dolphin calves and juveniles of both species. Fin Whales (*B. physalus*) were commonly observed in relatively large groups in 1997, but were uncommon or absent in other years. Humpback Whales (*Megaptera novaeangliae*), Blue Whales (*B. musculus*) and North Atlantic Right Whales (*Eubalaena glacialis*) were uncommon in the area, although Humpback Whales were sighted frequently in 1997. Increased numbers of White-sided Dolphins, Fin and Humpback whales in 1997 may be explained by increased prey abundance and decreased sea-surface temperatures.

Key Words: White-beaked Dolphin, *Lagenorhynchus albirostris*, Atlantic White-sided Dolphin, *Lagenorhynchus acutus*, Harbour Porpoise, *Phocoena phocoena*, Minke Whale, *Balaenoptera acutorostrata*, Fin Whale, *Balaenoptera physalus*, Humpback Whale, *Megaptera novaeangliae*, seasonality, group size, calves, Nova Scotia.

In temperate ecosystems, it is common for cetaceans to exhibit seasonal and annual fluctuations in their distribution and abundance (e.g., Hooker et al. 1999). These fluctuations are thought to be a reflection of seasonal changes in the environment, such as sea surface temperature (e.g., Hooker et al. 1999) and prey distribution (e.g., Kenney et al. 1996). Monitoring highly mobile, top level predators such as cetaceans serves not only to identify their habitat use patterns and track their population sizes, but also to monitor the health of the overall marine ecosystem.

The area between Halifax and Mahone Bay, Nova Scotia, is habitat for several species of cetaceans. It is used extensively by the commercial fishing industry, commercial shipping (especially near Halifax Harbour) and recreational boaters, and it is being used increasingly for whale watching. Given the high potential for anthropogenic influences in the Halifax area, there is good reason to study and monitor cetaceans there.

Methods

Field Methods

Data were collected from 1996 to 2005, primarily from 1 June to 30 September. From 1996 to 1999, 12.6 m and 14 m whale watching vessels were used to make three 3-hour trips daily, weather permitting. In 2000 and 2001, an 8.5 m auxiliary sailing vessel was used, and in 2002 to 2005 a 4.2 m rigid inflatable boat was used. The latter two vessels were used only for research, and cruises in 2000 to 2005 were generally conducted only in weather conditions suitable for photo-identification. All surveys were limited to daylight hours and the area bounded by approximately 44°19' to 44°38'N latitude and 63°15' to 64°10'W longitude (Figure 1). The path of all vessels was opportunistic, based on where cetaceans were previously sighted. In 1996, only date, time, species, group size and the presence of calves and juveniles were recorded. In subsequent years, latitude and longitude positions were recorded (using GPS) for hourly search effort and species positions and photo-identification data were collected. Only those sightings identified to species level were included in analysis.

Animals were classified as adults, juveniles or calves. For odontocetes, first year calves were identified by having a length of <50% of adult body length, while juveniles were identified by having 50% – 70% of adult body length (Reeves et al. 1999; Lien et al. 2001; Bjørge and Tolley 2002). The identification of calves was often facilitated by their position near an adult, with younger calves displaying "chin-slap" surfacings, and in the case of neonatal calves, by fetal folds and bent-over dorsal fins (Weinrich et al. 2001). For mysticetes, calves were identified by having a length of

<40%, and juveniles by having a length of 40% – 60% of adult body length (Aguilar 2002; Clapham 2002; Perrin and Brownell 2002).

Over the ten-year study period, changes in methodology introduced several biases to our data. Data collected from the whale watching boats (1996-1999) were particularly problematic as the boat returned several times per day with new passengers to the same area where cetaceans had previously been sighted, potentially causing groups to be double-sampled and introducing a positive bias to calculations of hourly sighting rates. Cetacean encounters on the whale watching vessels were typically shorter in duration, and therefore a larger proportion of time was spent searching for new groups, introducing another potentially positive bias. However, the whale watching vessels were more likely to operate in inclement weather than the research vessels, which should negatively bias the sighting data. Larger groups were preferred on whale watching cruises, positively biasing group sizes. Vessel cruising speed also varied greatly in the nine year study period (ranging from 5 to 15 knots). These differences in survey speed changed our spatial sampling greatly, and therefore likely affected the sighting data. The height of observers above the sea surface also varied greatly, from a minimum 1.25 m to a maximum 5 m. Search effort varied greatly between different years and months, and as a result time periods with low effort may have had unreliable sighting rates (see Table 1a and 1b).

Calculation of Sighting Indices

Because of these biases, regular group sighting rates (sightings per hour) would not be directly comparable. Therefore, the data were restricted in order to calculate a "sighting index" for each species per year and per month. Potential positive biases from repeated sampling of the same cetaceans throughout the day were eliminated by daily scoring each species as present or absent. This restriction also reduces biases introduced from differences in vessel speed, and time spent searching vs. time spent with groups of cetaceans. Calculated sighting indices could range from a maximum of 1.0 (sightings occurring every day of field effort) to 0.0 (no sightings). In order to determine if weather significantly affected sighting rates, the sighting rates during good weather and bad weather were subjected to a chi-squared test. Good weather was defined as visibility ≥ 1 km, wind ≤ Beaufort 3 (≤ ≈ 19 km/hr), wave height ≤ 0.75 m, and swells ≤ 1.5 m. Results from this test indicate that sighting rates were significantly lower in poor weather ($\chi^2 = 0.9999$, df = 5, $0.025<P<0.05$). Therefore, in order to reduce bias due to weather conditions, only sightings during good weather were included in analysis. Consequently, the sighting index was calculated as the proportion of good weather days each species was observed, and serves as an indicator of relative abundance. Data from 1996 and 2000 were not included in the analysis, as the environmental data were not collected frequently enough to determine if specific sightings occurred during good weather. In addition, any year or month in which the effort was less than or equal to five days and any species with less than or equal to 10 sightings in total were omitted from analysis as results from these would likely be unreliable (Table 1).

FIGURE 1. Location of study area.

Analysis

Chi-squared tests were used to test the null hypothesis that monthly and yearly sightings were random. Group sizes and the proportions of groups with calves, juveniles and total sub-adults (calves + juveniles) were also calculated for all species observed more than 10 times. Data were restricted to one randomly selected sighting per day in order to reduce biases caused by repeated sightings of the same group and by selection for larger groups by the whale watching vessels. In addition, these calculations were conducted only on sightings which lasted five minutes or longer, as it was difficult to accurately estimate group size and presence of sub-adults during shorter encounters. Group sizes and the proportion of groups with calves and juveniles were calculated both for all selected sightings and for selected sightings which occurred during good weather conditions. As the differences in the results of these two methods were negligible, the full data set was used for analysis of group composition and size.

Results

Between 1996 and 2005, eight species of cetaceans were sighted during 1715 hours (309 days) in the field.

White-beaked Dolphins (*Lagenorhynchus albirostris*), Atlantic White-sided Dolphins (*L. acutus*; henceforth referred to as White-sided Dolphins), Harbour Porpoises (*Phocoena phocoena*) and Minke Whales (*Balaenoptera acutorostrata*) were observed in most years although annual and seasonal variations were observed (Tables 1a and 1b). Fin Whales (*B. physalus*) and Humpback Whales (*Megaptera novaeangliae*) were observed occasionally, and Blue Whales (*B. musculus*) and North Atlantic Right Whales (*Eubalaena glacialis*) were observed only rarely (Tables 1a and 1b).

Annual sighting indices of White-beaked and White-sided dolphins, Harbour Porpoises, Minke Whales, Fin Whales and Humpback Whales were significantly different from random (Table 2a). White-beaked Dolphins were sighted more frequently in 2003 and 2004 and White-sided Dolphins were sighted more frequently in 1997 and 2002. Harbour Porpoises were observed more commonly in 2002 and 2005, and Minke Whales were observed more commonly in 1999 and 2004. Fin and Humpback whales were sighted more frequently in 1997.

Monthly sightings of White-beaked and White-sided dolphins, Fin Whales and Humpback Whales were significantly different from random (Table 2b). White-beaked Dolphins were observed more frequently than expected early in the summer (June and July), while White-sided Dolphins were sighted more frequently than expected late in the summer (July through September). Fin Whales were observed more frequently than expected in August and September, and Humpback Whales were seen more frequently than expected in August. Monthly sightings did not differ significantly for Harbour Porpoises and Minke Whales.

White-sided Dolphins were found to have the largest mean group size of 46.5 (± 46.19 SD), and the highest proportion of groups with calves (0.354). Harbour Porpoises had the smallest group size of the odontocetes (mean = 2.7 ± 1.78 SD). Mysticete group sizes were typically smaller than odontocetes and only a few juveniles and no calves were observed (Table 3).

Discussion

White-beaked and White-sided Dolphins, Harbour Porpoises and Minke Whales were found in all years in which more than seven days were spent in the field (Table 1a). This suggests that the Halifax area was an important summer habitat for these species, while Fin Whales, Humpback Whales, Blue Whales and North Atlantic Right Whales were occasional visitors. Although some significant temporal variability found in this study cannot be directly explained, several interesting trends were noticed.

Annual Variation

White-sided Dolphins were unusually abundant in 1997, along with Fin and Humpback whales (Table

TABLE 2. Effort and number of presence/absence sightings using data set restricted as outlined in methods, (a) for year and (b) for month (pooled across years). Sighting indices (proportion of good weather days each species seen) shown in brackets. "*" indicates non-random distribution ($P<0.005$).

2a). Several ecological correlates may explain the increases in these three species. Sea surface temperatures for Halifax Harbour were significantly lower in 1997 than in 1998 and 1999 (MANOVA p = 0.002 daily minimum, $P < 0.001$ daily maximum; Ocean Data Inventory Database, Department of Fisheries and Oceans Canada). In addition, Coakes et al. (2005) attributed the abundance of Fin Whales in the study area to a local increase in Herring (*Clupea harengus*), Sandlance (*Ammodytes americanus*) and euphausiids (possibly *Meganyctiphanes norvegica*). These species are also potential prey items of Humpback Whales (Kenney et al. 1996), and White-sided Dolphins are known to prey upon Herring and Sandlance (Reeves et al. 1999). In 1997, we observed mixed feeding aggregations containing all three species, which has also been observed in the Gulf of Maine (see Kenney et al. 1996).

Seasonal Variation

The most noticeable trend in the monthly sightings was the temporal differences in the observations of White-beaked and White-sided dolphins (Table 2b). White-beaked Dolphins were seen more often than expected in early summer and were rarely observed in August. Even within the full data set, this species was not observed after August (Table 1b). This observation may be related to water temperature, as White-beaked Dolphins appear to prefer colder water (Lien et al. 2001). However, the species was less commonly observed in 1997 when water temperatures were lower (Table 2a). The seasonal movements of White-beaked Dolphins are not well understood. Large numbers occasionally become ice-entrapped in Newfoundland in February and March (Hai et al. 1996), they are seen further offshore on Grand Bank in May and June (Whitehead and Glass 1985), and they occur along the coast of Labrador from late June to at least August (Alling and Whitehead 1987). Since the 1970s, the species has been rare in the Gulf of Maine (Kenney et al. 1996), although several recent sightings and strandings in the Bay of Fundy (personal observation) and the southern Gulf of Maine (Waring et al. 2004) suggest a possible return of White-beaked Dolphins to these portions of their historical range. They also appear to be rare in offshore Nova Scotian waters (Hooker et al. 1999; Lucas and Hooker 2000). Although these observations suggest that the White-beaked Dolphins in our study area may winter in the Gulf of St. Lawrence and disperse into other areas in the spring, an offshore or more southerly wintering ground cannot be ruled out (Lien et al. 2001), and different populations may have different migratory patterns.

In contrast to the White-beaked Dolphins, White-sided Dolphins appear to prefer the later part of the season; first seen in July, commonly observed in August and September, and still observed in October (Table 1b). This seasonal trend is similar to observations in

TABLE 3. Mean group sizes and proportion of Dolphin groups with calves present and with any sub-adult present.

	White-beaked Dolphin	White-sided Dolphin	Harbour Porpoise	Minke Whale	Fin Whale	Humpback Whale
Group Size	9.1	46.5	2.7	1.8	5.9	1.6

the Gulf of St. Lawrence (Kingsley and Reeves 1998). However, in offshore areas of Nova Scotia the trend is reversed, and White-sided Dolphins are more common in the early summer (Hooker et al. 1999). This suggests a potential inshore-offshore migration for White-sided Dolphins in Nova Scotian waters. A similar migration has been suggested for the Gulf of Maine (Kenney et al. 1996). An alternate explanation is the existence of distinct coastal and offshore populations, each with its own migratory pattern, as seen in Common Bottlenose Dolphins (*Tursiops truncatus*; Wells and Scott 1999). However, as White-sided Dolphins are observed in April in the Gulf of Maine (Weinrich et al. 2001), the dolphins observed in our study area could also originate from further south.

The seasonal trends observed in the two dolphin species partially explain variations in annual sightings. For example, in 2000 White-beaked Dolphins were not observed (Table 1a). However, the first day of field work was not until late July, reducing the probability of observing the species that year.

In all years, temporal separation of the two dolphin species was observed, and they were rarely seen on the same day, with only one mixed group observed in the ten-year study period. Similar observations of temporal separation have been observed between White-sided Dolphins and Short-beaked Common Dolphins (*Delphinus delphis*; Gowans and Whitehead 1995), and between Common Bottlenose and Dusky dolphins (*Lagenorhynchus obscurus;* Würsig and Würsig 1980). This temporal separation could be due to seasonal changes in environmental or ecological conditions. Over a larger time scale, changes in water temperature and preferred prey species were thought to explain an increase in White-sided Dolphin abundance and a decrease in White-beaked Dolphin abundance in the Gulf of Maine (Kenney et al. 1996). However, some overlap in feeding ecology is possible (Northridge et al. 1997), and temporal separation may be a means of reducing competition by partitioning resources (Roughgarden 1976). In this case, a competitive exclusion relationship may exist, as suggested by Kingsley and Reeves (1998) for White-beaked and White-sided dolphin populations in the Gulf of St. Lawrence.

Fin Whales were seen more frequently than expected in August and September, while Humpback Whales were seen more frequently in August (Table 2b). These results are generally consistent with the migratory patterns of Humpback and Fin Whales (Aguilar 2002; Clapham 2002). Harbour Porpoises and Minke Whales showed no significant seasonality, suggesting that these species may be present in the study area for a longer season.

The temporal sighting patterns observed in this study were compared with stranding data from the Marine Animal Response Society of Nova Scotia (T. Wimmer, unpublished data). All species observed in this study stranded at least once in the study area between 1996 and 2004, with the exception of the rarely observed Humpback, Blue and North Atlantic Right whales. Several species that were not observed alive did strand in our study area between 1996 and 2004: Common Bottlenose Dolphin, Pygmy Sperm Whale (*Kogia breviceps*), Pilot Whale (likely Long-finned, *Globicephala melas*) and Sei Whale (*B. borealis*; although two Sei Whales were tentatively identified in the study area in August 1997). Most strandings occurred in July and August both within the study area and in the surrounding areas, months when cetaceans were most commonly observed at sea (Table 2b), although search effort for strandings was also highest in the summer. No strandings occurred in the study area from January to March, although search effort during these months was low. The only species that stranded in the study area late in the year (October – December) were White-sided Dolphins, Minke Whales and Fin Whales. We also observed these species at sea in the late summer and fall (Table 1b and 2b). Fin and Minke Whales have also been observed at sea in the study area during the winter (personal observation).

Group Sizes

White-beaked Dolphins were commonly found in groups of 10-20 animals in the western Atlantic (Lien et al. 2001), and the observed group size in this study

(mean = 9.1; Table 3) was similar to that found in the Gulf of St. Lawrence (aerial surveys, mean = 8.65; Kingsley and Reeves 1998). For White-sided Dolphins, the observed group size (mean = 46.5; Table 3) was similar to that reported in the Gulf of Maine (mean = 52; Weinrich et al. 2001). These group sizes were higher than those observed in the Gulf of St. Lawrence (mean = 8.25; Kingsley and Reeves 1998) and in offshore areas of Nova Scotia (mean = 8.8, Hooker et al. 1999). These observations support the idea of a seasonal migration into our study area from the Gulf of Maine, and/or ecological similarities between the two areas. However, group sizes were unusually high in 1997, and group sizes since 1997 have been smaller (mean = 32.3 ± 38.96 SD), also supporting the hypothesis that feeding conditions were unusually good in 1997. Harbour Porpoise group size (mean = 2.7, Table 3) was similar to other observations (e.g., mean = 2.42; Kingsley and Reeves 1998).

The group size found for Fin Whales (mean = 5.9; Table 3) was larger than many other studies in the western Atlantic (e.g., Gulf of St. Lawrence mean = 1.89; Kingsley and Reeves 1998, offshore Nova Scotia mean = 1.3; Hooker et al. 1999). The larger mean group size in this study may be due to the whale watching vessel having selected for larger groups. Consequently, smaller groups were likely omitted from our analysis as they often fell below the five minute threshold. A similar bias was discussed by Bérubé et al. (2001), who selected for larger groups of Fin Whales in the Gulf of St. Lawrence and found a mean group size of 5.89. Since 1997, fin whales were found in smaller groups (mean = 2.3 ± 1.89 SD), as was more common in other areas, again suggesting that our observations of larger group sizes were likely linked to high prey abundance in 1997. Group sizes for Minke and Humpback whales (mean = 1.8 and 1.6, respectively; Table 3) were typical for these species (e.g., Kingsley and Reeves 1998).

Calf and Juvenile Presence

Calves and juveniles were commonly observed in groups of White-beaked and White-sided dolphins (Table 3), consistent with the calving seasons for these species (Reeves et al. 1999; Lien et al. 2001). Given that dolphins have long juvenile stages relative to the time spent as yearling calves, it is not unexpected that more White-beaked Dolphin groups contain juveniles than calves (Table 3). The presence of two neonatal calves (identified by bent dorsal fins) in June indicates that the area at least occasionally serves as a calving ground for this species. White-sided Dolphins had a much higher proportion of groups with calves (35.4%). Young calves in "echelon position" were commonly seen in this species, and several calves with fetal folds have been observed in July and August. This suggests that these dolphins are in the study area for the peak of their calving season, and that the study area is an important nursery area for this species. White-sided Dolphin calves were less common than in the Gulf of Maine, where 41.4% of all groups contained calves, and 51.5% to 56% of groups contained calves between July and September (Weinrich et al. 2001). Far fewer groups in our study area contain juveniles (10.4%) than calves, supporting the hypothesis that juvenile White-sided Dolphins are segregated from other age classes, as suggested by Sergeant et al. (1980). Harbour Porpoise calves were observed far less frequently (16.7%; Table 3) than in the Bay of Fundy (63%; Gaskin and Watson 1985). This could be due in part to differences in research focus and methodology, and that our study area is more exposed, potentially making detection more difficult. Baleen whale sub-adults were rare during the study period (Table 3) and difficult to identify as the young were frequently far from adults. The scarcity of young calves of these species is consistent with their rapid body growth rates and what is known of their migration and calving patterns (Aguilar 2002; Clapham 2002; Perrin and Brownell 2002).

Acknowledgments

We thank the many people who have helped with field work, especially Lars Bejder, Amanda Coakes, Joe Lake, Luke Rendell, Hal Whitehead, Heidi Williams, and the staff and owners of Peggy's Cove Water Tours. S. G. was supported by The Natural Sciences and Engineering Research Council. The American Museum of Natural History, Canadian Wildlife Federation, Eckerd College, PADI Project AWARE, Illford Canada and Mountain Equipment Co-op Halifax supported this project. Tonya Wimmer provided access to stranding records, and Margie Hardie, Leszek Karczmarski, Hal Whitehead and Bernd Würsig provided helpful input for this manuscript. This paper was improved by the reviews of Jon Lien and two anonymous reviewers.

Winter Habitat Use by American Marten, *Martes americana*, in Western Alberta Boreal Forests

GILBERT PROULX

Alpha Wildlife Research & Management Ltd., 229 Lilac Terrace, Sherwood Park, Alberta T8H 1W3 Canada

Proulx, Gilbert. 2006. Winter habitat use by American Marten, *Martes americana,* in western Alberta boreal forests. Canadian Field-Naturalist 120(1): 100–105.

Although the American Marten (*Martes americana*) is found in most forest regions of Alberta, little is known about its choice of winter habitats. This study investigated winter habitat use by American Marten in Weyerhaeuser's Grande Prairie Forest Management Area (FMA) using snowtracking along 128.2 km of seismic lines inventoried in winters 1999, 2002, and 2005 with snowmobiles. American Marten tracks ($n = 44$) occurred significantly less frequently than expected ($P < 0.001$) in immature/young pole stands, but more frequently than expected ($P < 0.02$) in mature/old growth mixedwood stands. American Martens apparently used young forests, and mature/old coniferous and deciduous stands, according to their availability. Forest development plans should be developed locally to retain late successional forests that meet the winter habitat requirements of American Marten.

Key Words: American Marten, *Martes americana,* forest management, winter habitat, Alberta.

Studies in coniferous forests of western North America suggest that American Martens (*Martes americana*) prefer late successional stands with vertical and horizontal structural complexity (Proulx et al. 2004). Koehler and Hornocker (1977) in Idaho, Campbell (1979) in Wyoming, and Koehler et al. (1990) in Washington reported that the highest level of American Marten activity was associated with mature Englemann Spruce – Subalpine Fir (*Picea engelmannii – Abies lasiocarpa*) forest type. In California, Spencer et al. (1983) concluded that optimal habitat for American Marten was extensive late successional forest. In British Columbia, most studies reported that American Martens used late successional coniferous forests. In the Sub-boreal Spruce Biogeoclimatic Zone, Lofroth (1993) found that American Martens preferentially included mature to old-growth forests in their home ranges. Proulx et al. (2005) described American Marten winter habitats in this biogeoclimatic zone as late-successional, circum-mesic stands with relatively high canopy closure and/or basal area. In the Boreal White and Black Spruce Biogeoclimatic Zone of northeastern British Columbia, Therrien (2002) found that American Martens preferred mature mixedwood forests. On the other hand, Poole et al. (2004) found that American Martens preferentially used mature coniferous forests but otherwise appeared to use all forested stands relative to their availability, including extensive deciduous and mixedwood stands <40 years of age.

Although American Marten is an important furbearer found in most forest regions of Alberta, little is known about its choice of winter habitats. I investigated winter habitat use by American Marten in Weyerhaeuser's Grande Prairie Forest Management Area (FMA) using snowtracking. On the basis of previous studies conducted in western North America, I hypothesized that American Marten tracks would be found mainly in late-successional forests.

Study Area

The Grande Prairie FMA (55°11'N, 118°53'W) is a 1 145 600-ha area located in northwestern Alberta, along the British Columbia border (Figure 1). Relief varies greatly, from undulating in the north and northeastern portions of the FMA, to mountainous areas, with elevations exceeding 1350 m in the south and southwest. Half of the FMA has a subhumid, continental climate with short, cool summers and long, cold winters (Alberta Government 1999*). The southern and southwestern half of the FMA has a subalpine climate, with below freezing temperatures occurring in all months and winter precipitation often exceeding 200 cm of snowfall (Alberta Government 1999*). The FMA is located within the Boreal vegetation zone, characterized by Engelmann Spruce, White Spruce (*Picea glauca*), Black Spruce (*Picea mariana*), Subalpine Fir, Balsam Fir (*Abies balsamea),* Lodgepole Pine *(Pinus contorta)*, and Trembling Aspen (*Populus tremuloides*) in both pure and mixed stands (Looman and Best 1987; Alberta Government 1999*).

Methods

Snowtracking was conducted from 4 to 16 January 1999 (15 transects ranging in length from 0.2 to 8.7 km; total: 41.1 km), 12 to 27 February 2002 (14 transects ranging in length from 0.5 to 7.1 km; total: 36 km), and 20 January to 9 February 2005 (25 transects ranging in length from 0.8 to 4.3 km; total: 51.2 km). The number and length of inventory transects varied according to accessibility, safety, and environmental conditions. These corresponded to randomly selected 6-m wide seismic lines distributed across the FMA. The

FIGURE 1. Location of Weyerhaeuser's Grande Prairie Forest Management Area (FMA) and inventoried regions in western Alberta.

same regions were investigated during the three inventories (Figure 1). A few seismic lines were used repeatedly over the years. In most cases, however, this was not possible because of access problems (overgrown vegetation, inappropriate snow conditions, or interfering gas exploration or logging activities), or transformation of seismic lines into roads or pipelines. Habitat type classification along inventory transects was based on Proulx and Kariz (2005) (Table 1).

Transects were traversed by snowmobiles (<10 km/h). We recorded only tracks that were well-defined and judged to be fresh; i.e., less than 24 h old (subjective assessment based on the experience of the researcher). Due to the similarity between Fisher (*Martes pennanti*) and American Marten footprints (Halfpenny et al. 1995), when mustelid tracks were encountered, they were investigated on both sides of transects and within forest stands to find the best tracks available. The combination of footprint (pattern and size, presence absence of toe pad prints) and trail (gait, distance between jumps, and dragging of the feet) characteristics were used to identify tracks (Murie 1975; Rezendes 1992; Halfpenny et al. 1995). Fisher tracks are usually larger and farther apart, although the footprints of female Fishers and male American Martens may be of similar size. In winter, the undersurface of American Martens' feet is heavily covered with hair and toe pads do not show (Murie 1975; Rezendes 1992). The undersurface of Fishers' feet has sparse hair, and pads show well in clear prints (Halfpenny et al. 1995). Compared to American Martens, Fishers tend to walk more, leave straight trails, create troughs when walking in soft snow, drag their feet, and leave tail drag-marks in the snow (de Vos 1951; Raine 1983). Compared to American Martens, Fishers seldom tunnel under the snow (Halfpenny et al. 1995). Scats found on trails were also used

TABLE 1. Habitat types used in the study of American Marten winter habitat use in 1999, 2002, and 2005 in Weyerhaeuser's Grande Prairie Forest Management Area, Alberta (after Proulx and Kariz 2005).

Forest type	Characteristics
Deciduous	Crown closure ≥ 10%, deciduous species > 75%.
Coniferous	Crown closure ≥ 10%, coniferous species > 75%.
Mixedwood	Crown closure ≥ 10%, neither type > 75%
Habitat type	**Description**
Immature-Pole	0-40 years old stands. Open areas and new stands. Pole stands are thick stands of trees (7.5 to 12.4 cm diameter at breast height), usually with little understory.
Young	40-80 year-old forests. Achievement of dominance by some trees and death of other trees leads to reduced competition that allows understory plants to become established. The forest canopy has begun differentiation into distinct layers. Vigorous growth and a more open and multi-storied stand than in the pole stage.
Mature-old	≥ 81 years old late successional stands consisting mostly of mature stands with even canopy of trees, with or without coarse woody debris down and leaning logs. A few old stands with tall and large canopy trees, canopy gaps, large snags, large downed woody debris, and developed understories. A second cycle of shade tolerant trees may have become established.

to identify animals. When encountering animals, footprints and trails were studied to ascertain criteria used to differentiate American Marten from Fisher.

Autocorrelation may occur during analysis of track survey data because of the uncertainty in whether one or more animals have made the tracks being counted (Proulx and O'Doherty 2006). It is sometimes difficult to confirm that a series of tracks along a transect belongs to the same animal (de Vos 1951), as home ranges overlap (Buskirk and Ruggiero 1994), and winter dispersal movements are known to occur (Clark and Campbell 1976). On the basis of track characteristics, Proulx et al. (2005) deduced that tracks of two different animals could be as close as 100 m from each other along the same transect. To minimize spatial autocorrelation, only tracks >100 m apart within the same forest stand were recorded (Bowman and Robitaille 1997; Proulx et al. 2006).

In western North America, American Martens appear to be associated with late successional stands. Consequently, I hypothesized that American Marten tracks would not be distributed at random among habitat types, but that they would be more frequent in mature and old-growth stands. My hypothesis was declared before examining the track survey data. The proportion of inventory transects within each habitat type was used to determine the expected frequency of track intersects/habitat type (i.e., availability) if tracks were distributed randomly with respect to habitat types (Proulx et al. 2006). For each survey, I used a one-tailed Fisher Probability test (Siegel 1956) to compare the proportion of American Marten tracks in the habitat growth types, i.e., mature/old vs. immature/young. Data from the three inventories were pooled to increase sample size. Chi-square statistics with Yates correction (Zar 1999) were used to compare observed to expected frequencies of track intersects among habitat type. If the chi-square analysis suggested an overall significant difference between the distribution of observed and expected frequencies, comparisons of observed to expected frequencies for each habitat class were conducted using the G test for correlated proportions (Sokal and Rohlf 1981). Probability values ≤ 0.05 were considered statistically significant.

Results

Temperatures ranged from -21°C to 0°C and snow depths exceeded 45 cm during each inventory. Inventories were conducted ≤ 24 h after snowfalls or flurries, thus assuring that tracks were fresh.

In 1999, 41.1 km of transects were inventoried: 27.8 km (67.6%) in immature/young stands, and 13.3 km (32.4%) in mature/old stands. Eight tracks were recorded: 3 (37.5%) in young stands, and 5 (62.5%) in mature-old forests. The observed distribution of tracks was not significantly ($P = 0.31$) different from a random distribution of tracks among habitat types.

In 2002, 36.0 km of transects were inventoried: 16.6 km (46%) in immature/young stands, and 19.4 km (54%) in mature/old stands. Ten tracks were recorded: 1 (10%) in a young stand, and 9 (90%) in mature/old forests. The observed distribution of tracks was not significantly ($P = 0.07$) different from a random distribution of tracks among habitat types.

In 2005, 51.1 km of transects were inventoried: 27.1 km (53%) in immature/young stands, and 24 km (47%) in mature/old forests. Twenty-six tracks were recorded: 6 (23%) in young stands, and 20 (77%) in

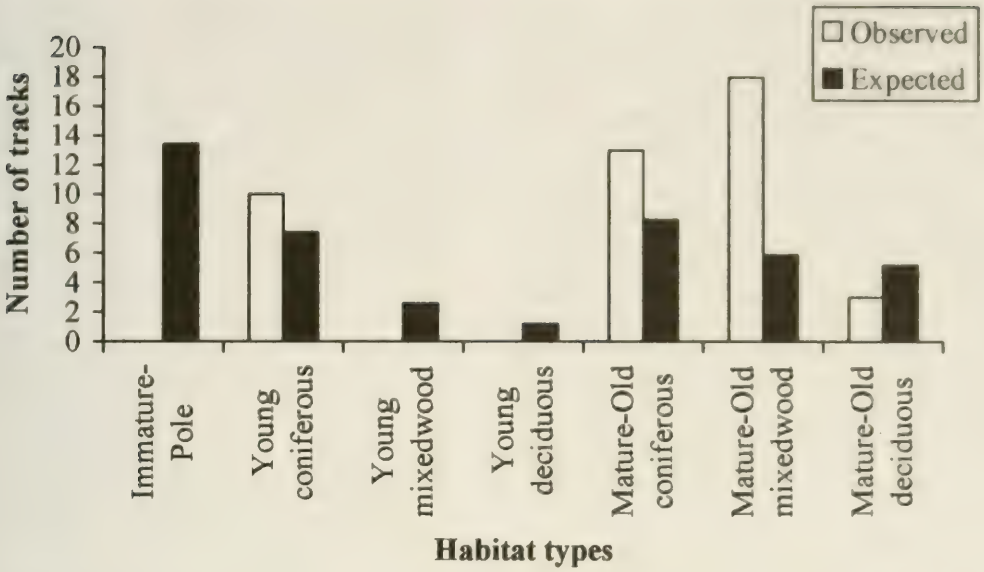

FIGURE 2. Observed and expected number of American Marten tracks per habitat type in Weyerhaeuser's Grande Prairie Forest Management Area.

nature-old forests. The observed distribution of tracks was significantly ($P = 0.002$) different from a random distribution of tracks among habitat types.

A total of 128.2 km of transects were inventoried from 1999 to 2005: 39.1 km (30.5%) in immature/pole stands, 32.5 km (16.9 % in coniferous, 5.8% in mixed coniferous-deciduous, and 2.7% in deciduous) in young stands, and 44.2 km (18.8% in coniferous, 13.5% in mixed coniferous-deciduous, and 11.9% in deciduous) in mature/old forests. Forty-four tracks were recorded: none in immature/pole stands, 10 tracks (22.7%) in young coniferous forests, and 34 tracks (77.3%) in mature/old stands (Figure 2). The observed distribution of American Marten tracks was significantly different from a random distribution of tracks among habitat types ($\chi^2 = 39$, df: 4, $P < 0.001$) (Figure 2). Tracks were significantly less frequent than expected in immature/pole stands (G = 17.2, df: 1, $P < 0.001$), and more frequent than expected in mature/old mixedwood stands (G = 6.42, df: 1, $P < 0.02$). The distribution of tracks suggested that American Martens used young forests, and mature/old coniferous and deciduous stands, according to their availability.

Discussion

In 1999 and 2002, because of small sample sizes, no significant difference was found in the distribution of American Marten tracks among habitat types. However, during both years, most tracks were in mature-old forests. Pooling data increased sample size and statistical power, and showed that American Marten tracks were definitely more frequent in late-successional stands. This finding is in agreement with previous studies conducted in western coniferous forests (Spencer et al. 1983; Wilbert 1992; Koehler et al. 1990; Therrien 2002; Proulx et al. 2006). American Martens prefer mature and old-growth forests over young and immature forests because this is where they maximize foraging efficiency and finding rest sites that can protect them from harsh environmental conditions (e.g., Powell et al. 2003).

Although young forests are believed to be suboptimal due to a reduction of necessary structure and diversity compared to mature and decadent forests (Thompson and Harestad 1994), in this study, nearly a quarter of American Marten tracks were located in young coniferous stands. As late/successional stands are decreasing in importance in Weyerhaeuser's FMA due to timber harvest, and oil and gas exploitation, American Martens may have to make greater use of young forests. However, previous studies showed that American Martens used young forests in winter where sufficient physical structure (Bowman and Robitaille 1997; Poole et al. 2004) and prey (Potvin et al. 2000) were present. More research on the characteristics of young forests used by American Martens is required to better understand their importance as winter habitat for this species in boreal ecosystems.

The fact that no tracks were recorded in immature and pole stands is in agreement with previous studies that have generally shown that American Martens make little or no use of early/successional stages

(Steventon and Major 1982; Thompson 1994; Thompson and Harestad 1994; Chapin et al. 1998; Heinemeyer 2002; Poole et al. 2004). Previous studies have also shown that American Martens appear intolerant of habitat fragmentation, and they would not tolerate more than 30-35% cutovers in their home range (Snyder and Bissonette 1987; Hargis and Bissonette 1997; Chapin et al. 1998; Potvin et al. 2000; Poole et al. 2004). In Weyerhaeuser's FMA, mature and old forests may be highly fragmented due to extensive clearcuts, and an important network of seismic lines and roads. Undoubtedly, these habitat modifications would have an impact on the distribution of American Martens, and cause shifts in home range boundaries (Poole et al. 2004). Forest development plans taking into consideration the winter habitat requirements of American Marten should therefore be developed locally according to the distribution of late/successional forests, cut blocks, and access networks (e.g., Proulx 2001*).

Acknowledgments

Burchsted, J. C. A., and Fred Burchsted. 2006. Lady Crabs, *Ovalipes ocellatus*, in the Gulf of Maine. Canadian Field-Naturalist 120(1): 106-108.

The Lady Crab (*Ovalipes ocellatus*), mainly found south of Cape Cod and in the southern Gulf of St. Lawrence, is reported from an ocean beach on the north shore of Massachusetts Bay (42°28'60"N, 70°46'20"W) in the Gulf of Maine. All previously known Gulf of Maine populations north of Cape Cod Bay are estuarine and thought to be relicts of a continuous range during the Hypsithermal. The population reported here is likely a recent local habitat expansion.

Key Words: Lady Crab, *Ovalipes ocellatus*, Gulf of Maine, distribution.

The Lady Crab (*Ovalipes ocellatus*) is a common member of the sand beach fauna south of Cape Cod. Like many other members of the Virginian faunal province (between Cape Cod and Cape Hatteras), it has a disjunct population in the southern Gulf of St. Lawrence (Ganong 1890). The Lady Crab is of considerable ecological importance as a consumer of macrobenthic invertebrates, and is of biogeographic interest as a member of a large disjunct fauna. However, the distribution of the Lady Crab in the Gulf of Maine is unclear from the literature. Here we gather and discuss available reports of the Lady Crab in the Gulf of Maine and report an additional site that may represent a recent habitat expansion. This paper is intended as a basis for further work on Lady Crab distribution and for monitoring changes.

Lady Crabs have not generally been reported from the Gulf of Maine. Field guides (Gosner 1978; Meinkoth 1981; Miner 1950) and a review of tidal flats (Whitlatch 1982) give their northern limit as Cape Cod except for the disjunct Gulf of St. Lawrence population. Recent distributional studies of Gulf of Maine crabs show Lady Crabs on the south shore of Cape Cod and onto Georges Bank but no further north (Williams and Wigley 1977; Stehlik et al. 1991). This confirms the older work of Rathbun (1930). Williams (1984), and the update by Nizinski (2003), give the range briefly as Prince Edward Island to Georgia, but in this they may elide the northern New England gap. Pollock (1998) states the range as Virginian and Acadian, but again the range between the southern Gulf of St. Lawrence and Cape Cod is unspecified. The Lady Crab is not listed in Bay of Fundy, Maine, and New Hampshire checklists (Croker 1972; Brinkhurst et al. no date; Linkletter et al. 1977; Perkins and Larsen 1975) and distributional studies of the fauna of Maine sand beaches (Larsen and Doggett 1990) and mud flats (Larsen and Doggett 1991). Lady Crabs were not found in intensive local studies of western Cape Cod Bay (Davis and McGrath 1984) or Ipswich Bay (Dexter 1944).

Berrick (1986) reports Lady Crabs as common on Cape Cod Bay sand flats (which commonly reach 20°C in summer). The few other published records of Lady Crabs in the Gulf of Maine are from warm, estuarine habitats. Bousfield and Thomas (1975) identify a group of three warm water species which tend to co-occur (*Balanus improvisus, Urosalpinx cinera*, and *Ovalipes ocellatus*) but do not specify locations for the Lady Crab. Members of this group occurred in 1963 at: Cape Cod Bay, Duxbury and Cape Ann (Massachusetts); Cape Neddick and Boothbay Harbor (southern Maine); and the Bay of Fundy. Bousfield found Lady Crabs at Sesuit Harbor, East Dennis, Massachusetts, in 1964 (Judith Price, personal communication). Lady Crabs are reported in Salem Sound, Massachusetts, in 1997 by Chase et al. (2002). Although Dexter (1947) found no Lady Crabs in an intensive study of a tidal inlet at Annisquam (Gloucester, Massachusetts) in 1933-1940, he later (Dexter 1985) found them there during what he terms a period of warm water from 1952 to 1964.

We have found Lady Crab shells washed up on an ocean beach adjacent to the Essex and Ipswich river estuaries (Crane Beach, Ipswich, Massachusetts, 42°41'30"N, 70°46'20"W; 1995 and 1996). Fefer and Schettig (1980) mention, but do not specify, one or more southern Maine (south of Saco) locations from unpublished data by Doggett, Larsen, and Sykes. They were not found in the 1873 U.S. Fisheries Bureau investigation of Casco Bay which discovered several other warm water species (Verrill 1874). There are no records for the northern Maine cold water region (north of the Sheepscot River estuary) identified by Bousfield and Laubitz (1972) and confirmed by Larsen and

Doggett (1990). In the northern Gulf of Maine, there are several reports of Lady Crabs in the Bay of Fundy: Bousfield and Leim (1960) report Lady Crabs in the Minas Basin and Channel in 1922 (Bass River and Scotman Bay, noted also in Rathbun 1930) and again in 1959 (Bass River, Diligent River, and a cheliped on beach at Kingsport).

Bousfield and Thomas (1975) state that their Gulf of Maine records of Lady Crabs are from warm (circa 20°C summer temperatures – similar to their range south of Cape Cod) brackish water pockets or from estuaries with two-layer circulations where endemic warm-water populations could be maintained as described by Bousfield (1955) and Sponaugle et al. (2002). Bousfield and Thomas (1975) suggest these estuarine populations are relicts from the Hypsithermal warm era (9500-3000 years Before Present). The many Virginian invertebrates and marine algae now extending north to Cape Cod with additional disjunct populations in the southern Gulf of St. Lawrence had continuous ranges at that time. The short abstract by Dexter (1985) provides no details, but his 1952-1964 warm period may correspond to the 1951-1954 warming reported by Loder et al. (2001), with the crabs becoming locally extinct during the succeeding cold period (1959-1967). Dexter's observations suggest the possibility that the estuarine distribution is dynamic, populations becoming extinct and reestablished with changing conditions.

For the ten years we have been keeping records, Lady Crabs have been commonly found living on an ocean beach, called Preston Beach in Marblehead and Phillips Beach contiguously to the south in Swampscott, on the north shore of Massachusetts Bay (42°28'60"N, 70°46'20"W). There is no nearby estuarine habitat and the beach is exposed to heavy surf (unlike the Cape Cod Bay flats) [Leo et al. 2003]. Salem Sound is about six coastline miles to the north around the headlands of Marblehead/Marblehead Neck. This is the first reported exposed ocean beach location for Lady Crabs in the Gulf of Maine. Phillips Beach is in an area of wind-driven summer upwelling that keeps summer temperatures around 15-16°C (Geyer et al. 1992). Lady Crabs were commonly found swimming in shallow water and buried in sand just above low tide line. The habitat is thus very like that of the Lady Crab south of Cape Cod. Most of the living animals were found on the southern portion of the beach. This area is influenced by groundwater seepage on the high beach. Old faunal lists for Swampscott and vicinity yield no records of Lady Crabs: Grabau (1898) for Nahant, Revere, and Phillips Beach; Pearse (1913) for Nahant. This suggests our Massachusetts population may mark a local habitat expansion.

Discovery of other ocean beach populations and determination of the status of the estuarine populations would help clarify the distribution and habitat associations of Lady Crabs in the Gulf of Maine.

Acknowledgments

We thank E. L. Bousfield for information on his collections and Judith C. Price of the Canadian Museum of Nature for searching the collections for Lady Crab records.

Ring-billed Gull, *Larus delawerensis*, Food Piracy on Diving Ducks

WILLIAM J. WALLEY

222 Bossons Avenue, Dauphin, Manitoba R7N OR2 Canada

Walley, William J. 2006. Ring-billed Gull, *Larus delawerensis*, food piracy on diving ducks. Canadian Field-Naturalist 120(1): 109-110.

One of four Ring-billed Gulls observed 26 April 2002 at Dauphin Lake, Manitoba attacked a group of diving ducks and took abandoned food items.

Key Words: Ring-billed Gull, *Larus delawerensis*, Common Goldeneye, *Bucephala clangula*, kleptoparasitism, Manitoba.

Kleptoparasitism or piracy is the forceful taking of food by one species of bird from another (Terres 1980). According to Bent (1921) Ring-billed Gulls (*Larus delawerensis*) have been observed to hover over feeding ducks, notably Red-breasted Mergansers (*Mergus serrator*) darting at them as they re-surfaced apparently to steal their prey although success is not reported. Although Ring-billed Gulls do not usually pirate other gull species (Ryder 1993) they have been observed pirating food from European Starlings, *Sturnus vulgaris* (Burger and Gochfeld 1981). Clapp et al. (1983) state that a variety of species are pirated by the Ring-billed Gull. Jarvis and Southern (1976), in their study of the food habits of this gull in the Great Lakes region, made no mention of piracy or attempted piracy during the breeding season.

Crescent Cove at the south end of Dauphin Lake (51°10'N; 99°53'W) in west central Manitoba was windless and sunny but cold (-11°C) at mid morning on 26 April 2002. There, 15 m from shore, a stretch of water 70 m in length and 30 to 50 m in width had opened up parallel to a sandy beach. Small numbers of grebes and diving ducks, about 5 and 25 respectively, swam about on the calm surface, some diving for food. Ring-billed Gulls were also on the water, stood on the edge of the ice, or flew around in the area.

Upon my arrival on the nearby ridge above the beach 2 Red-necked (*Podiceps grisegena*), 3 Horned grebes (*Podiceps auritus*), 3 Redheads (*Aythya americana*), and 5 Canvasbacks (*Aythya valisneria*), and unhurriedly swam away leaving a half dozen Common Goldeneyes (*Bucephala clangula*) and 3 Greater Scaup (*Aythya marila*). With the ducks diving and returning to the surface, a Ring-billed Gull, only one of four gulls believed to actually be an attacker, typically took wing off the surface from among the waterfowl and flew low toward a duck up to 15 or 20 m away where it had just surfaced. Upon reaching the targeted bird, the gull flew up and hovered just above and behind its head as described by Bent (1921). The duck plunged out of sight and the gull, using its bill, snatched the food item surrendered. One attack was initiated from as close as 1.5 m.

Often a duck surfaced without prey and with several ducks diving it was remarkable how quickly and efficiently the gull identified a successful duck from the others and attacked it. Two prey items were identified: crayfish (Decapoda) and small fish which, when plucked from the water, were eaten on the spot after the gull alighted on the surface nearby or flew to a shelf of ice where the item was tossed down, re-grasped, then swallowed.

During the forty minute observation, attacks on the diving ducks were initiated 20 – 25 times. With one exception – a female scaup – all attacks targeted the goldeneyes. Other than one instance where four male goldeneyes directed a threat display involving the thrusting of their heads low over the water toward a nearby gull, little aggression was shown by the ducks. Avoidance of contact and hence injury from the gull attacks appeared to be paramount for the ducks. Frustration on the part of the ducks was not in evidence, but determination to capture more prey was.

In April at Dauphin Lake, carrion, notably discarded coarse fish from ice fishing activities, would seem to be an important source of food for early arriving carnivorous or omnivorous birds from the south such as gulls, Bald Eagles (*Haliaeetus leucocephalus*), American Crows (*Corvus brachyrhyncos*) and some species of hawks, in addition to resident populations of the Common Raven (*Corvus corax*). A possible shortage of fish and/or other sources of food in the Crescent Cove area of the lake and, perhaps, on the lake ice generally due to competition, may have been a factor in the gulls' attacks on the goldeneyes. Observations of the lake from shore at Crescent Cove with the use of a 20 power spotting scope that day revealed only one such food item, the carcass of a Canada Goose (*Branta canadensis*) lying on the ice 250 m out. In immediate succession at this source of carrion, included: a Northern Harrier (*Circus cyaneus*) with two crows nearby; an adult Bald Eagle that causing the harrier to fly off and three immature Bald Eagles that displaced the adult eagle at the carcass; all to the exclusion of any gulls, suggesting intensive competition for food. This competition may have resulted in the unusual method of securing food observed in at least one Ring-billed Gull.

Acknowledgments

I thank Ken Kingdon of Parks Canada, Riding Mountain National Park, for literature concerning the

Ring-billed Gull – Red-breasted Merganser record. Appreciation is also extended to A. J. Erskine and other reviewers whose constructive comments were well received.

Probable Black Bear, *Ursus americana,* Retrieval of an Elk, *Cervus elaphus,* Carcass from a Small Lake in Riding Mountain National Park, Manitoba

WILLIAM J. WALLEY

222 Bossons Avenue, Dauphin, Manitoba R7N OR2 Canada

Walley, William J. 2006. Probable Black Bear, *Ursus americana,* retrieval of an Elk, *Cervus elaphus*, carcass from a small lake in Riding Mountain National Park, Manitoba. Canadian Field-Naturalist 120(1): 110-112.

Strong circumstantial evidence indicated that a sow Black Bear (*Ursus americana*) retrieved an Elk (*Cervus elaphus*) carcass from near the middle of a small lake to feed herself and three cubs.

Key Words: Black Bear, *Ursus americana,* Elk, *Cervus elaphus,* carcass, small lake, Riding Mountain National Park.

Accounts of observations of Black Bears (*Ursus americana*) retrieving carcasses from bodies of water are difficult to locate, even those based on circumstantial evidence. Studies of food habits of Black Bears by Hatler (1972) and Machutchon (1989) cite no such instances. Herein is provided a description of a series of observations that lead to the conclusion that an Elk (*Cervus elaphus*) carcass was brought to shore from mid-lake by a female Black Bear.

The observation reported was made at Grayling Lake (50°47"N, 100°W) in Riding Mountain National Park, Manitoba. This is a kettle lake (Lang 1974) and as such is deep (9 m) for its small surface of approximately 25 hectares. It is situated well below surrounding rolling hills in mixed forest about 9 km north of Clear Lake. With the exception of an 80-m gap to the NW and the lake outlet through sedge and grass meadows to the north, tall spruce (*Picea*) trees encircle and shelter Grayling Lake.

At 0815 on 2 August 2004 under full sunshine a large object was seen floating just west of the middle of the lake by the author and two companions from north-south orientated Highway 10 that passes just to the west of the lake (Figure 1).

Identification of the brown-gray object was not made even with 8 × 40 binoculars. At 12:15 that day the lake was re-visited. Though air movement was almost negligible, the object had been moved close to the east shore, where two Coyotes (*Canis latrans*) fed on it. Some 50 m to the north, a Black Bear was unhurriedly walking north away from the carcass and the Coyotes. It then disappeared into heavy coniferous forest. Shortly after, the Coyotes moved off and a bear appeared at a small partial clearing above the shore and the carcass. In subsequent days the bear, from this point, repeatedly chased off Coyotes but tolerated the intensive food collecting activity of a pair of Common Ravens (*Corvus corax*). On 3 August a sow led her three cubs to the carcass, where they fed.

In the next few days the remains of the carcass were identified as cow Elk (*Cervus elaphus*) by Ken Kingdon

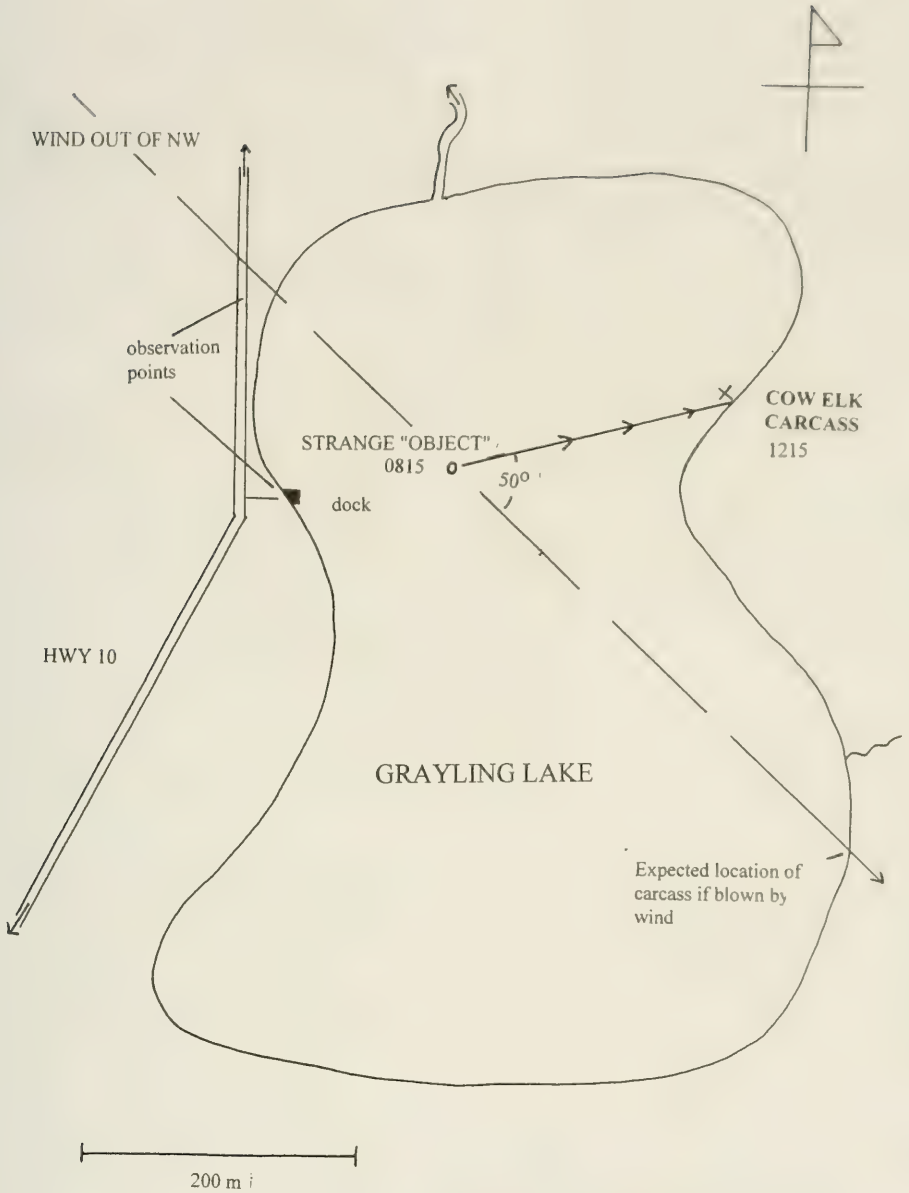

FIGURE 1. Elk carcass locations relative to wind direction, Grayling Lake, 2 August 2004.

of Parks Canada (personal communication) and independently by the author.

It was hypothesized that the bear had retrieved the carcass from the lake and had to swim out at least 200 m to get it. Veteran Parks Canada Warden Pat Rousseau (personal communication), an expert on Black Bears, concurred. In his experience he had not actually seen bears drag Elk carcasses ashore but, from an aircraft, had seen a Black Bear swimming halfway out toward an Elk carcass 40 m from the shore of a lake. On another occasion he had seen Black Bear and Gray Wolf (*Canis lupus*) tracks associated with an Elk carcass on the shore of a remote lake in the park. In the mid-1990s a party of hikers reported an animal with a black head behind a carcass in deep water of Bead Lake Four less than 3 km NW of Grayling Lake. The only scavenger other than a bear that it might have been mistaken for would be the much rarer Wolverine (*Gulo gulo*) (Pat Rousseau, personal communication).

Environment Canada wind data in the critical time period that day (08:00–12:00) showed only very light breezes primarily from the NW which almost certainly eliminated the wind as being a factor in the carcass being blown to the east shore (Table 1) (Figure 1). On

a similarly calm day, 13 August, blocks of wood were placed in the middle of the lake to see if water currents would carry them to the east shore.

No definitive proof was obtained that the bear swam out and hauled the carcass a minimum of 200 m to shore. However, the negative results of the water currents experiment coupled with the data on wind direction and speed that day provided a strong suggestion that this is what happened. Still, it is possible that another species of scavenger (e.g., Wolverine) brought the carcass to shore, and then abandoned it. Further, although none was seen before 08:15 or after 12:15 there is a possibility that, while the carcass was unobserved by the author between these times that day, one or more people kayaking or canoeing on the lake took the carcass to the east shore. Interviews with such recreationists at the lake on subsequent days revealed no knowledge of the carcass being moved. Hence, both of these scenarios seem very unlikely.

In retrospect, the bloated condition of the carcass near the middle of Grayling Lake on 2 August doubtless produced a powerful olfactory stimulus for the bear and her cubs.

Acknowledgments

I thank Parks Canada Warden Patrick Rousseau for his accounts of Black Bears and Elk and Warden Service Communications Officer of Riding Mountain National Park, Ken Kingdon, for providing information on wind speed and direction. Appreciation is also extended to the reviewers of the manuscript who made constructive comments and gave suggestions.

ZOOLOGY

The Birds of East Africa: Kenya, Tanzania, Uganda, Rwanda, Burundi

By Terry Stevenson and John Fanshawe. 2006. Princeton University Press: 41 William Street, Princeton, New Jersey, 08540 USA. 640 pages U.S. $35.00 Paper.

Birds of East Africa: Kenya, Tanzania, Uganda, Rwanda, and Burundi is one of a number of bird guide books on this region. Indeed, this publication is a paperback version of the award-winning 2001 hardback edition. It has not been updated.

The first of these books I bought was *Birds of East Africa* by Williams and Arlott, published in 1963. At the time I was very pleased at the style and quality of this work. Some 665 species were illustrated. In 1999 this was superseded by *Birds of Kenya and Northern Tanzania* by Zimmerman, Turner and Pearson. This book was a giant leap forward with 1084 species illustrated (even though this only covered 40% of the area of East Africa.) The illustrations increased by 419 species despite the smaller area covered. Also the quality of the artwork and printing was far better and was a closer match to European and North American guides. Now we have the new *Birds of East Africa* with Norm Arlott again providing much of the artwork. This volume illustrates 1388 species and is another, although smaller leap forward.

Birds of East Africa covers the resident, migrant, and vagrant bird species of Kenya, Tanzania, Uganda and the two smaller countries of Rwanda and Burundi (the area of these two together is less than 3% of the region, but adds a surprising number of species to the list). The text is high quality and faces the colour plate page (a more convenient format). The species accounts describe identification, status, range, habits, and voice. The colour distribution maps are small, but clear.

The question now arises, which is the better book for the visitor going on typical trips to the major parks in Kenya and northern Tanzania? *Birds of Kenya and Northern Tanzania* is slightly smaller (around 5%) and covers less territory. While this loses about 20% of the species, most of these are specialist species confined to Uganda, Rwanda and Burundi (about 225 species that are wholly or primarily confined to those countries). The remainder are species predominantly from southern Tanzania.

To my eye the artwork in *The Birds of East Africa* is noticeably better both for the colourful species and the LBJ's ("Little Brown Jobs": warblers and Cisticolas), but this not a huge difference. I checked several species from my slide collection and found *Birds of East Africa: Kenya, Tanzania, Uganda, Rwanda, Burundi* was generally more accurate. The user will find it very difficult to separate Long-billed from Tawny pipit using *Birds of Kenya and Northern Tanzania*, but will find only a small improvement with *Birds of East Africa* as these birds are difficult to separate anyway.

There is not much to choose between the texts (although it is more extensive in *Birds of Kenya and Northern Tanzania*) and the coverage of endemics is very similar. It is easier to have the text, illustration and map side by side (*Birds of East Africa*). The biggest difference lies in the range maps. The *Birds of East Africa* shows only a single range designation, covering winter, summer and migratory ranges. In comparison, *Birds of Kenya and Northern Tanzania* shows summer and winter ranges separately. Just as important, *Birds of Kenya and Northern Tanzania* more clearly defines where the birds are located. For example waterside birds like bitterns and herons are show in localities where water occurs. Similarly plains species are shown in the plains. The *Birds of East Africa* maps blanket the entire area that water birds can occur giving the impression they can be anywhere, even in dry savannah.

Birds of Kenya and Northern Tanzania includes a map of region inside its front cover that shows the key locations mentioned in the text. Although *The Birds of East Africa* has maps that show features (like forest cover), they do not depict the location of national parks, cities, etc. Neither book gives alternative names, which is a bit irritating when making comparisons with park checklists, older books, trip reports etc. (e.g. *Schoenicola brevirostris* is called the Fan-tailed Grassbird or Broad-tailed Warbler and not to be confused with *Cisticola juncidis* called the Fan- tailed Warbler but now known as the Zitting Cisticola.)

If you are planning a trip that includes Kenya, Tanzania, Uganda, Rwanda or Burundi, *The Birds of East Africa* is the more valuable book to take with you. When I go to Kenya and Tanzania later this year, the extra information given by the range maps would prove beneficial (These more detailed range maps will be particularly useful for the first time visitor.), but I am taking *Birds of East Africa: Kenya, Tanzania, Uganda, Rwanda, Burundi* because of ease of use and higher accuracy of the illustrations.

2193 Emard Crescent, Beacon Hill North, Ottawa, Ontario K1J 6K5 Canada

The Birding Sites of Nova Scotia

By B. Maybank. 2005. Nimbus Publishing Ltd., 3731 Mackintosh St., Box 9166, Halifax, Nova Scotia B3K 5M8 Canada. 654 pages, $35.

There is a path that runs from a popular beach in southern Nova Scotia. If you know exactly where, you can leave this path and cross several hundred metres to the start of a more secret path. This second path runs through a spruce grove along a cliff. If you know exactly which spruce to slip behind, you will find a hidden rope that will allow you to drop several metres down a cliff face. You will be in a very secluded cove with a golden beach and blue water, sheltered from any cold wind. This secret spot must be the only place in Nova Scotia that Blake Maybank has not visited! His new book is an incredibly detailed set of directions to (almost) every tiny nook of this beautiful province.

The main purpose of this book is to give sufficient directions for the visitor or native Nova Scotian to find the numerous coves and special places that dot the province. This is not as easy as it sounds as some of the roads and tracks are obscure and hard to distinguish. For example, I know native-born people who did not know of the track to Cherry Hill Beach, even though they had driven past it many times. This is because it is tucked between houses and looks like a driveway. Very sensibly Maybank has given the GPS coordinates of this location and others where someone might have trouble.

At each locality the author describes the habitat and comments on the birds typically to be found there. He also includes cultural highlights such as churches, lighthouses, museums and other tourist attractions. Although the title suggests this book is only about birds, Maybank includes similar information on mammals, butterflies, reptiles and amphibians. Where noticeable he comments on the wildflowers but this is not a focus. Each section has icons representing the types of birds, plants or mammals found and other key features like washrooms to be found on the site.

Giving directions can, of necessity, be dry reading even (or especially?) when they are given in great detail. The writer's style is much more upbeat and entertaining in the other sections. I was amused to read (Meat Cove) is "beyond the radar ... its delights are shared by a privileged minority" (Meat Cove, despite its name, is indeed a beautiful place of seabirds, orchids and gorgeous scenery; naturalists should certainly go there). Maybank does not give a detailed account of all the birds likely to be seen at a given locality. He uses generic terms such as gulls, shorebirds and warblers. However he has set up a website where you can access bird lists and information on the key localities. I assume he plans to keep this site current, so it is much more useful then putting a list in the book (which would soon be dated).

There are a few items that I think need changing. Page 243B has lost part of its text, an obvious printing problem. The author states "There are no deer ticks ... hence no Lyme disease." It is not this simple. Dog ticks (*Dermacentor variabilis*) also carry the Lyme disease bacteria, *Borrelia burgdorferi* (technically they are "infected", but maybe not "infective"). Whether or not the *D. variabilis* tick transmits Lyme disease is not yet resolved, suggesting caution. I was dismayed to see he did not mention Grassy Island (and hence Roseate Terns) in his account of Pearl Island (perhaps the last pair has been extirpated). The book has no index, meaning you will need a map to get you oriented. (Find the county you want and use the index to get you to the correct chapter.)

Any traveler who has gone to the expense of traveling to Nova Scotia needs this book; it will be invaluable. They will get to more places and see things they would have missed. Nova Scotians will also benefit. I doubt if anyone has traveled so widely and could provide such a precise record as Maybank. I will be using this book for my upcoming trip to Ile Madame in Cape Breton. As my last trip was in winter, I look forward to more informed and interesting birding this time.

The Complete Fauna of Iran

By Eskandar Firouz. 2005. I. B. Tauris. London, New York. xiv + 322 pages. US $90.

This book covers the vertebrate fauna of Iran, mammals, birds, reptiles, amphibians and freshwater fishes. It is a revised, English language version of a 2000 publication by the same author in Farsi (reviewed by Coad and Keivany 2002). Those fluent in Farsi might prefer that version at the bargain price of $5.63!

Iran is a country that often appears in the political news for its great economic and strategic geographical importance. This is mirrored in its vertebrate fauna, which includes such famous economic species as the caviar-bearing sturgeons and many diverse species of interest to naturalists close to its location at the intersection of the Palaearctic, Ethiopian and Oriental realms.

The Introductory sections of the book are particularly valuable for readers not familiar with this part of the world, and encompass 48 pages. A transliteration system is explained for the Farsi common names of organisms (a local language name list is always useful as scientific names may be more of a barrier than a

help outside academia), the distribution of Iranian provinces is mapped, major freshwater drainage basins outlined, and topography summarized in colour. A summary of zoological work in Iran follows with accounts of the transition between hunting and falconry to conservation and protection. Iran now has an impressive list of 16 National Parks, 13 National Nature Monuments, 33 Wildlife Refuges and 92 Protected Areas. Summaries of physical geography, climate, vegetation, zoogeography, threatened species and some fossils follow, illustrated by colour habitat photographs. Appendix I lists all the parks, their area, year established and a grid reference for a map in the Introductory section. Appendix II describes the Pardisan project (from the Old Persian for paradise), a 270-ha park in Tehran intended to replicate Iranian environments as an innovative educational project and centre for research in all fields related to the natural world. Conceived by Firouz, Pardisan was meant to be an academy of sciences, a zoo, herbarium, aquarium and museum. Hopefully it will come to fruition. The Bibliography encompasses 7 pages and is a general introduction to the literature on Iran. This literature is surprisingly diverse and could not be covered in this book – that on freshwater fishes, for example, numbers over 2900 items (see www.briancoad.com). The book ends with indices to Latin and English names of vertebrates and a general index.

The mammals occupy 60 pages, birds 88, reptiles 54, amphibians 10 and freshwater fishes 34. The number of mammal species referred to is 168, birds 514, reptiles 199, amphibians 20, and freshwater fishes 173, for a total of 1074. Because of space limitation, not all species are described. Introductory sections give an overview of work on each group and an update from the 2000 edition in Farsi; e.g., six species of mammals have been added to the fauna. Iranian scientists became very active in the 1990s and subsequently, as evidenced by their publications in such journals as *Zoology in the Middle East*. Comments are made on conservation and the destruction of habitats that threaten so many species, here as in the rest of the world.

As an example, the first family dealt with, the hedgehogs, number four species which are listed by English name, Farsi name in English script, Latin name and a numbered listing of the provinces in which they occur. This requires the reader to find the map of provinces at the front of the book, and these maps are very small (15 by 10 mm), and would require a knowledge of Iranian geography to interpret easily. Any illustrated species is indicated by a diamond next to the English name. A general review of hedgehog biology precedes this list. No mention is made of the absence of hedges in Iran (where hedgehogs are found in burrows, bushes and rock crevices), and the disconcerting habit shown by some species of hissing loudly when disturbed is also omitted, an attribute not noted in the more sedate English hedgehogs.

Mammals of note, and evidence of the land bridge that Iran forms between Europe, Asia and Africa, include lions and tigers (both now, sadly, extinct), Egyptian fruit bats, wolves, red foxes and jackals, cheetahs, leopards and lynx, hyenas and badgers, deer and gazelles, and jerboas and hares. The plan to re-introduce lions from India to southern Iran is noted but not whether this actually took place. Rumours in the 1970s had them introduced, but quickly wiped out by local villagers who were not ardent conservationists when faced with a potential predator on their sheep and goats, not to mention sleepy goatherds and shepherds. The illustrations are a mix of photographs and colour drawings.

The birds are illustrated mainly from colour drawings provided by Birdlife International and are a good summary of that fauna. Necessarily, this section in particular must be quite abbreviated in its text, given the bird diversity, but books devoted to birds are widely available for the fauna of the Middle East. Status symbols are given for each species rather than provincial distributions as with mammals; e.g., R = common resident, r = scarce resident, again a system that requires reference back to the page listing 16 possibilities. These could certainly have been included with each species' name in an abbreviate form.

The reptiles are well-illustrated with colour photographs. The fauna is varied and interesting but not evident without effort in field situations. I seldom saw snakes and lizards while living in Iran although small geckos could be found on house walls (and had a ferocious bite). One of the largest lizards readily encountered is the Bengal Monitor which reaches 2.75 m. Chasing one of these rapid lizards across the desert could be quite tiring if they did not try to hide behind a bush much too small to conceal their length. Marsh crocodiles live in the southeast of Iran, much decimated by drought in the late 1990s. They are here reported as not attacking people, a fact I wish I had known in the 1970s when I might have sampled their home streams for fish less nervously. Five species of marine turtles are known from the Persian Gulf, all badly in need of protection.

The amphibian fauna is small in species although toads and frogs are common in and near water. Tree frogs are found on banks of streams, trees being rare in much of desert Iran.

Extensive critical comment on the freshwater fishes would be inappropriate given the input by this reviewer. Only freshwater fishes are dealt with, although this includes Caspian Sea fishes where salinities are about one-third of sea water. The diverse fauna of the Persian Gulf and Sea of Oman are not covered—a recent summary work is Assadi and Dehqani Posterudi (1997). One loss of information is that space does not always allow for a full explication of evocative Farsi names. The enormous sturgeon, *Huso huso*, reaching 1.5 tonnes and 6 m in length, is known as fil mahi which

translates appropriately as elephant fish while the pike, *Esox lucius* is ordak mahi, duck fish from its duck-like snout.

The author is eminently qualified to write on this topic having been the Director of the Department of the Environment and vice-president of IUCN. He is regarded as the father of Iran's environmental movement. The Farsi version of this book won the Iranian Publisher's Association top award.

This book is highly recommended as a well-written overview of a fascinating fauna.

Fishes of the World

By Joseph S. Nelson. 2006. John Wiley & Sons, Hoboken, New Jersey. Fourth Edition. xvii + 601 pages. U.S. $125.

This book covers all the 515 families of fishes in the world in 62 orders and 5 extant classes. Fossil families are more briefly treated. Each class, subclass, order, suborder, family and subfamily receives a brief description. In this way the reader is treated to a tour of the world's fishes through their higher classification and relationships. This being the fourth edition, 30 years after the first, proves the need, and success, of such a work. Scientists and students look to this work for an overview of fish classification and, with an estimated 28 400 species at the end of 2006 compared to about 26 730 tetrapods (mammals, birds, reptiles and amphibians), the fishes need this structure. At the individual species level, constantly changing as new ones are described or old ones revised, the online "Catalog of Fishes" from the California Academy of Sciences is the update source (www.calacademy.org/research/ichthyology/catalog/index.htm).

A website, http://members.shaw.ca/fishesoftheworld/index.htm contains errata, a list of new families post-1958, student exercises and links to relevant websites. Changes in the numbers of taxa between the four editions of the book are listed in the table below.

Variation in the number of families is mostly due to lumping and splitting as Nelson points out at the website mentioned above. Discovery of new families is a rarity in fishes. However, the estimated number of known fish species for the end of 2006 cited above is almost 10 000 more than in 1976, showing that this field of endeavour has been most active.

The text has continued to be expanded over the earliest editions, with families once without a description now provided with one. Much necessarily remains the same from the last edition as relationships, anatomy and species content remain unchanged in certain families. Not all genera are listed within each family, although a couple listing would be a great convenience, and not all families have a line drawing (about 74% do). Some families have undergone significant changes, with new information on species numbers, ecology and fossil members added, including the new coelacanth found in a fish market. Several groups (e.g., Characiformes, Osphronemidae) have been rearranged based on new systematic studies, and Nelson makes a concerted effort to follow a cladistic framework. However, as Nelson notes in his preface, it is naïve to accept the latest proposals as being the best. Nelson has used his own considerable judgment in determining which groups are sufficiently systematically stable to include. This has also resulted in some families (e.g. Cichlidae) losing some structure, as new studies have shown past taxonomic groupings to be non-monophyletic.

The literature on fish classification is extensive, sometimes arcane in its arguments, and scattered in journals worldwide. Having an author mull over this literature and provide an interpretation and digest for consideration is a great service to students and to those professionals who need to dip into these waters at intervals.

In this new edition, Nelson has included many more references, providing the most recent literature. The Bibliography is comprehensive and covers 54 pages. Some authors may be disappointed that not all their papers are cited, but Nelson has generally included good summary papers that will provide, within their own references, many titles of more specific articles.

The Index at 63 pages is also most useful in locating particular taxa but certain genera will not be found (as noted above) and the reader will have to resort to *Catalog of Fishes*. Additionally, the previous edition used the names of orders as the running header throughout the text. The use of the more inclusive class level as the running header in the new edition is less helpful in flipping through to find the desired pages.

Year	Species	Freshwater	Marine and Diadromous*	Families	Orders	Classes
1976	18,818	6851	11,967	450	46	4
1984	21,450	8411	13,312	445	50	4
1994	24,618	9966	14,652	482	57	5
2005	27,977	11,952	16,025	515	62	5

The single disappointment of the new edition is the loss of the chart of categories and relationships of fishes from the inside front cover. It is now buried on (unnumbered) pages xvi-xvii, between the Acknowledgments and the Introduction, making it much harder to find. Owners of the book may want to place a permanent bookmark in the chart for quick reference. The new chart, while showing better resolution of groups in this edition, has also lost all the names between Class and Order. While some of these names were for non-cladistic grades, their presence on the previous edition's chart was of great benefit, particularly for students, to determine exactly what is a "teleost" or "actinopterygian", or any of the other names that are commonly used by ichthyologists.

At the end of the list of errata on the website given above, and on page 9 of the new edition, Nelson draws attention to the need for ichthyologists, and the work that still remains for future generations. He urges us to support the replacement of retiring ichthyologists to continue the work. The Introduction of *Fishes of the World* provides a sampling of all the rich areas of ichthyology to be studied and highlights the importance of fishes to all of us. Perhaps if the Introduction were required reading for everyone, Nelson's enthusiasm for fishes would be passed on to all, and the worth of ichthyological research would be clearly visible to governments and society. This book continues to be a seminal work, finding an essential place in libraries and on the bookshelves of anyone interested in fishes.

BRIAN W. COAD and ALISON M. MURRAY

Canadian Museum of Nature, Ottawa, Ontario K1P 6P4 Canada

Insects: Their Natural History and Diversity: With a photographic guide to insects of eastern North America

By Stephen A. Marshall. 2006. Firefly Books Ltd., 66 Leek Crescent Richmond Hill, Ontario L4B 1H1 Canada. 720 pages. Can $95. Hardcover.

It has always been said that you can't judge a book by its cover, but after reading *Insects: Their Natural History and Diversity* I've learned that this well-worn axiom isn't always true. When this book first crossed my desk, to say that I was instantly enamoured would be an understatement. It was so beautiful, the cover adorned with a stunning jewel-toned dogbane beetle (*Chrysochus auratus*). I almost didn't want to crack the binding. However my curiosity finally got the better of me and I'm glad it did because once I started reading I couldn't put the book down.

Visually stunning, with over 4000 color photographs of insects in their natural habitats, *Insects: Their Natural History and Diversity* has the look and feel of a glossy coffee table book while still being full of accurate, well researched information.

As its title implies *Insects: Their Natural History and Diversity* focuses on the diversity and natural history of common families of northeastern North American insects. The book opens with a brief synopsis of basic insect anatomy and morphology. This is followed by chapters covering the diversity of all insect orders, including all the major families, along with two chapters on non-insect arthropods and methods for observing, collecting and photographing insects. The book's last 50 pages are dedicated to illustrated keys to order and family as well as a key to the most commonly encountered insect larvae. These keys are designed to facilitate ease of use and therefore emphasize morphological characters visible to the naked eye or easily seen with a hand lens. Also peppered throughout the book are helpful suggestions on where to look for and find various insect orders/families. For example "Depending on your inclination and the weather, a good place to start looking for assassin bugs would be in your kitchen light fixture. Unless you are much more fastidious than most, the odds are that among the crispy critters accumulated there you will find a large black assassin bug called the Masked Bed Bug Hunter (*Reduvius personatus*)."

Considering that *Insects: Their Natural History and Diversity* is priced so as not to be cost prohibitive and is clearly written in plain language makes it highly accessible to a broad audience including naturalists, amateur entomologists as well as seasoned professionals. The author has also included a dollop of humour and wit throughout the text. For example this passage describing the appearance of springtails: "Some are covered with scales, like those of a butterfly, many are brilliantly colored and all are morphologically bizarre, starting from the long, forked tail used to make Herculean leaps, and ending with the deeply pocketed mouth that makes springtails look like they have lost their dentures and then sucked on a bunch of lemons."

This book would make a great textbook for a natural history or general entomology course. Especially when you consider that the impetus for this book centers on materials originally gathered in support of the author's third-year course "The Natural History of Insects" at the University of Guelph. With its depth of scope and true-to-life color photographs *Insects: Their Natural History and Diversity* would be indispensable in the field; however, due to its size it would be a bit unruly to have to lug around.

I thoroughly enjoyed this book and would recommend it whole heartedly to anyone who has an interest in entomology, natural history or a simple curiosity about the six-legged world that surrounds us.

Department of Biology, St. Francis Xavier University, Antigonish, Nova Scotia B2G 2W5 Canada

Secret Weapons – Defenses of Insects, Spiders, Scorpions, and Other Many-Legged Creatures

By Thomas Eisner, Maria Eisner, Melody Siegler. Belknap Press of Harvard University Press, Cambridge. 2005. 372 pages.

This book is dominantly about chemical defences of terrestrial arthropods, though other types of defences (camouflage, catapulting, sticky traps) are also mentioned. Chapters are short, and typically feature the defences of one organism, or at most a small group of related organisms. One or more colour photos, in themselves almost worth the cost of the book, enhance both the aesthetics of the book and the ability to drive home each chapter's message. Chemical formulae are illustrated in those chapters focusing on chemical defences.

As the subtitle alludes, an array of terrestrial arthropods is dealt with, but by far, the majority of this book is about insect defences. However, scorpions, centipedes and other non-insects together account for about 15% of the book's material. Examples include the well-known spray of the Bombardier Beetles, the less well-known vomit attacks of noctuid moth caterpillars and immobilizing wax of oleander aphids.

This book will appeal to a wide array of readers, the caveat being that those with no (or little) training in chemistry (like me) will miss out on some of the nuances of the chemicals themselves; this did not give rise to any problems at all for my enjoyment of this book. The other caveat being that those not liking those long, tongue-tripping scientific names of organisms will have to gloss over them periodically as they read; even where common names exist for the organism of the chapter's focus, the scientific name is typically used throughout the text. Grade-school children will be able to use this book though clearly not as completely as older folk; entomology instructors could easily incorporate this material into lectures. Truly, this book can meet the needs of many.

There is an abundant amount of fascinating material that simply makes this well-written book a joy to read; I have been equally satisfied after having read Waldbauer's books, including *What Good are Bugs?* (also from Harvard Press). Unlike the latter book, the chapter bibliographies of *Secret Weapons* are replete with papers of the book's authors, particularly the Eisners. Their work in chemical ecology, translated by them from their papers to this book, is a grand example of making science more consumable by the non-specialist.

RANDY LAUFF

St. Francis Xavier University, Antigonish, Nova Scotia B2G 2W5 Canada

Rodents and Lagomorphs of British Columbia

By David W. Nagorsen. 2005. Royal British Columbia Museum, Victoria, British Columbia.

I read this book both with a general interest in mammals overall, and, as a raptor biologist, a desire to more completely understand the creatures which are the prey of my birds. I was not disappointed on either account. From a simply presentational point of view, the artwork sticks out as being very aesthetically pleasing. Each species is illustrated with a pencil drawing of the complete animal – not in a standard three-quarter pose or profile, but in varying postures that show snapshots of each animal's character. Additionally, the skull of each species is presented in lateral, dorsal and palatal views – perhaps this is not useful to the general reader, but I certainly benefited from them; the illustrators (Michael Hames, Donald Gunn and Bill Adams) must be commended.

The book has three keys – one each for whole animals, skulls and chipmunk genital bones. Anyone who has used an unillustrated key understands the frustration of trying to interpret the author's meaning (what is meant by "relatively large?"). A fully illustrated key has diagrams for each couplet – the keys in this book are not fully illustrated, but there are plenty of diagrams that make the process of keying out an organism rather straightforward.

An introductory chapter describes the biogeography of British Columbia, along with conservation strategies, winter survival and several other topics which link these species together. Maps and good photographs are featured here.

The species accounts dominate this book. Each runs about six pages and describes physical aspects of the species, its natural history, geography, and conservation status. An occurrence map accompanies each account; I believe British Columbia residents and non-residents alike would have benefited from place names being included on the maps – especially those which are only mentioned once or twice in the whole book. Similarly, even the introductory maps do not include all the major sites mentioned in the book.

There are a small number of mistakes, some editorial (e.g. "supraorbital bone" is used instead of "supraorbital process"), some factual (e.g. "[The muskrat has] rooted cheek teeth."). In the introduction to the lagomorphs, I think it would have been appropriate to differentiate rabbits from hares.

I take particular exception to the oft-used expression that some introduced animal (in this book, the Eastern Cottontail) "seems to be filling an ecological niche." This is at best an empty comment (what introduced animal would not have a different ecology than the natives) and at worst could be interpreted as an excuse to tolerate and perhaps enhance introductions.

Those few shortcomings aside, this is a very good book which serves its purpose admirably. I will refer to it frequently.

RANDY LAUFF

St. Francis Xavier University, Antigonish, Nova Scotia B2G 2W5 Canada

Tanagers, Cardinals, and Finches of the United States and Canada

By D. Beadle and J. Rising. 2006. Princeton University Press, 41 William Street, Princeton, New Jersey 08540 USA 196 pages, U.S.$29.95 Paper.

The authors use 200 selected photographs to complement text covering the biology, identification, molts, song and distribution of the tanagers, cardinals, and finches found north of Mexico. In all, forty-six species are covered. Of these, one is an introduced species and 31 are native residents of some part of North America. The remaining 14 are vagrants with five as Alaska specials and seven creeping north over the southern border.

I have just spent a couple of hours resolving an identification issue using about 20 photographs off the Internet (out of the 200 I found there) of a single species. Most of those photos were of limited use. Normally I find such photographs less useful than artwork because they are so influenced by light, angle and the condition of the specimen. However, my jaundiced eye is very impressed with the photographs in this book. I do believe that I would be able to separate female House and Purple finches using the photographs and text given in this book. Indeed I used this book to confirm that I had correctly identified a Hoary Redpoll I saw recently in the Arctic. The typical resident species are represented by several photographs taken at different angles thus giving the reader a better understanding of the bird.

The 31 residents each have a range map giving summer, winter, and permanent ranges. These are about 5.5 cm square and very readable and useful. There is a written description of range too, which adds more detail. I had no difficulty deciding I was at the northern edge of my Hoary Redpoll's range. The text is clear and provides great detail without wasted words.

The vagrants are similarly treated, but do not have a range map. Under distribution their normal range (outside of North America) is described, followed by a summary of their occurrence in North America, with additional details, such as precise locations and dates, where warranted.

This is a very useful supplementary guide (to the classical all-species field guides) for providing additional information on this group of birds. It is conveniently sized to carry in the field and will be especially useful in sorting out look-alikes such as Hoary and Common redpolls. It provides carefully organized and well-presented information to those who wish to learn more about these birds than is given in the typical field guide. This is the type of book that makes a most welcome present!

Wheatears of Palaearctic: Ecology, Behaviour and Evolution of the Genus *Oenanthe*

By E. N. Panov. Pensoft, Sofia, Moscow. 439 pages, U.S. $167.50

Wheatears are the quintessential Afro-Eurasian bird. Found anywhere there is open ground, the more desolate the better, wheatears make ideal subjects for ornithological study; indeed, according to the author they are among the most studied groups of passerines. They are easy to see and follow, they exhibit interesting behaviours, and, as a group, pose many riddles. How can up to four species with seemingly identical foraging behaviours co-exist in a relatively inhospitable habitat? Why in some species is there high sexual dimorphism and in others virtually none? What light can this group renowned for intra-species variation shed on the nature of polymorphism and its evolutionary origins? What are the advantages of a contrasty black and white plumage? How did one species of this desert loving family break through the oh so inhospitable for wheatears boreal forest to successfully colonize much of the Arctic including not once but twice in North America?

These and other questions are copiously answered in this book by E. N. Panov, a Russian scientist with a passion for this intriguing group. The book is divided into two parts, the first dealing with general features of wheatear biology, the latter providing detailed monographs on individual species or superspecies found in Eurasia. Between them, these sections cover every conceivable angle on wheatears, from the geographic distribution and origins of the group in its entirety through habitats, movements, social behaviour, reproductive behaviour to predators and parasites. Each monograph follows a template covering systematics, distribution, behaviour, nesting, and movements. The book is extensively illustrated with black and white sketches illustrating everything from behaviours, nest sites to plumage variations and is amply provided with sonograms, family trees, graphs and maps illustrating key points. There is also a section of 40 colour plates showcasing the array of arid habitats so beloved of the genus, portraits of selected species, and at least one picture of one being devoured by a snake. The book closes with a 14-page bibliography and an index helpfully divided into a general subject index as well as an index of animal names.

There are about twenty species of wheatear, with the exact number hard to pinpoint because of blurry lines with other turdidae such as saxicola ("stonechats") and uncertainty about the taxonomy of several closely related taxa. Taxonomic and genetic evidence suggests that the genus had its origins in Africa, where it may have emerged from an ancestor shared with redstarts. The large amount of variation and frequent contact zones within the genus suggest that there is an ongoing evolutionary process. The English name, which comes from the old English for white rump,

refers to the bold white "T" pattern which is characteristic of many members of the genus. Its Russian name, Kamenka, refers to the stony habitat they so love; their ability to cope with extreme conditions is witnessed by the fact for some 160 000 square kilometres in the Sahara the White-crowned Black Wheatear is the only breeding passerine, and the fact that the Northern Wheatear has successfully colonized arctic tundra. Given the lack of culinary choice their dietary habitats are pretty well catch as catch can; recorded food items include scorpions and bumblebees.

The Northern Wheatear, the only member of the genus in North America, is remarkable. Each year birds from Alaska, in the words of the author, "stubbornly make for their remote African homeland", an epic voyage that would exhaust an Arctic Tern. Birds nesting in Eastern Canada head in the opposite direction, and are the only Canadian passerine that winters in Africa. Being found in places where lots of ornithologists live; the Northern Wheatear is one of the better known members of the group. From these studies, we know that they maintain a frenetic lifestyle during the breeding season that can, in the far north, involve a 24/7 routine of zealously patrolling its borders while attending the needs of two females in widely separated territories. According to Panov, Wheatears are highly aggressive with a "low threshold for territorial aggression". To communicate with one another they have three different song groups and a remarkably varied repertoire of physical signals involving different postures and movements. The author also usefully informs us that they have an unpleasant taste, evidenced by experiments in which hornets were offered wheatear "meat".

It is disappointing that the author, demonstrably a competent illustrator and photographer, did not choose to include a series of systemic plates illustrating the various taxa and their variations. Another disappointment is that the author focused the species accounts on Eurasian taxa; one suspects that this reflects the author's research interests but also the fact that African taxa are relatively less well known. In the review copy the hatching on many of the maps was blurry, making them hard to figure out. Nonetheless, there are few errors in the book, although the fact that the title contains a grammatical error did not inspire much up front confidence.

This book is a scientific monograph primarily aimed at ornithologists. It poses, and proposes answers to a number of interesting ecological and behavioural questions and will be of great interest to anyone intrigued by evolutionary biology.

BOTANY

Giant Trees of Western America and the World

By Al Carder. 2006. Harbour Publishing Co., Madeira Park, British Columbia. 138 pages. $18.05.

Al Carder has been researching giant trees for a lot of his long career, collecting stories of large trees in the Pacific forest of North America, his home and main study area. This book is a sequel to his earlier work trying to record the dimensions of many of the world's largest trees now including more facts and more tree species. The book is ordered by continents and tree families to give the reader perspective of the variety of trees which have achieved huge dimensions, but many of which have disappeared in the past century.

A short anecdotal essay at the beginning puts Carder's agenda forward quickly. He has always been awestruck by the beauty and perspective of being among the largest trees and wants to preserve the memory of those trees for future ages. Sadly the largest specimens of any tree species are gone from our world due to commercial logging in the last two centuries and when single giant trees survived the logging, these succumbed to windstorms, having been left without the surrounding forests which protected and supported their growth over the centuries. In North America, Australia and New Zealand, the story of logging is the history of large trees and our most impressive forests, a history which has more to do with destruction of forests than the story of humans interacting with their environment.

The book is short with only one hundred and thirty pages devoted to describing the trees. Each tree description has an accompanying page with a diagram of the tree at its largest reported size and shape, each species being unique in shape. Fifty of those pages are devoted to the trees of North America with the other pages listing and describing the outstanding trees of other continents. North America is obviously Carder's first priority but his love of trees encompasses the entire world.

Many trees in England and Europe have been available for study to written history over the centuries and Carder has researched these written accounts to give us historical anecdotes from their long life. A Tule tree in Mexico with an opening in the trunk large enough to accommodate twelve horsemen when reported 375 years ago, and the Sweet Chestnut in Sicily whose spread of branches sheltered the Queen of Aragon and her escort of 100 horsemen over 600 years ago are two of the anecdotes which describe trees still standing. Whether the tree has records of growing to over 400 feet as the Douglas Fir or whether its claim is to have lived over 5000 years as the English Yew, the grandeur of the trees is given to us by Carder to

be considered, enjoyed and lamented as phenomena which have existed but sometimes passed us by.

I enjoyed reading about present and past giant trees and was entertained different times looking for interesting facts and diagrams. It is not a book to be read at one sitting, even though short, because the tree species stand alone and reading several is like reading a list which can go on too long. A short reading of one or two tree descriptions at each visit is sufficient with another few minutes reading the next descriptions at another time. Soon the book becomes a reference for tree species and musings of how much we have missed and what we might visit. I have shown it to my students and they spent time with it as a picture and description book to browse and marvel. Al Carder has given us a little gem of knowledge and history for entertainment based on good science and research.

ENVIRONMENT

Fire and Avian Ecology in North America – Studies in Avian Biology Number 30

Edited by Victoria A. Saab and Hugh D.W. Powell. 2005. Cooper Ornithological Society. 193 pages.

This technical work is a collection of 11 papers, ten of which address the role and effect of fire in one or more ecosystems (e.g., Boreal Forest, Oak Woodlands, Interior Chaparral); the first chapter is a cogent summary of the ten others.

The chapters more or less follow a logical pattern in their layout. Each paper shows a map of the distribution of the habitat(s) discussed, and normally one or two other figures. A table of pertinent literature is presented in each chapter, which also includes responses to fire of a number of bird species. The papers describe historic fire regimes, including the use of fire by aboriginals, as well as the effect of fire suppression on birds (and by default, the plants making up the habitat for them); sections on conservation strategies, including the use of prescribed burns and withholding of fire suppression end each chapter.

The only irritant to me was lumping all the references at the end of the book; normally, each paper should be concluded with its own collection of references. Should someone want to photocopy one chapter, they would have to photocopy the entire compilation of references, instead of just the pertinent ones. Nonethe-less, it is a solid work.

Fisheries Assessment and Management in Data-Limited Situations

Edited by G. H. Kruse, V. F. Gallucci, D. E. Hay, R. I. Perry, R. M. Peterman, T. C. Shirley, P. D. Spencer, B. Wilson, and, D. Woodby. 2005. Alaska Sea Grant, Fairbanks, Alaska. Publication Number: AK-SG-05-02. 958 pages. Price: $50.00 US, ISBN:156612-093-4.

Maintaining sustainable fisheries resources requires the combined efforts of scientists, fisheries managers and policy makers. Balancing fisheries growth and conservation is a difficult task, particularly in situations where available information is limited. Data-limited fisheries are often plagued by a lack of long-term data on the basic biology, ecology and productivity of the species that are relevant to these resources. A number of successful fisheries have been developed by combining a scientific background with robust policy management to successfully develop sustainable fisheries, even in situations where data is limited. However, newly developing and small-scale fisheries often operate without sufficient data to develop production models, assessment techniques and sustainable management strategies.

To address these challenges, a symposium entitled "Assessment and Management of New and Developed Fisheries in Data-limited Situations" was held in Anchorage, Alaska, in 2003. The purpose of this symposium was to share knowledge, research and management strategies for newly developing and small-scale fisheries by bringing together fisheries scientists, managers and policy makers from all over the world. The result is a proceedings book titled "Fisheries Assessment and Management in Data-limited Situations." Specifically, this book is a collection of forty-six peer-reviewed research papers that provide case studies and management considerations for fisheries with limited data. The book is divided into seven sections: (1) case studies of fishery failures and successes; (2) indicators of stock health and productivity from limited sampling programs; (3) involvement of fishermen and use of local knowledge; (4) multi-species and ecosystem indicators and models; (5) precautionary management approaches; (6) stock assessment models; and (7) stock assessment surveys and applications. The first two sections focus on science-based assessments of fishery case studies while the final five sections identify and discuss management and assessment strategies. Throughout many of the case studies in this book, several key management themes emerge that are highly relevant to fisheries managers in data-limited situations.

Section one provides insight into the failures and successes of the world's fisheries. Several case studies on a variety of species are described, and management implications are discussed. A key paper in this sec-

tion provides a general overview of the world status of data-limited fisheries using landings statistics with a Bayesian approach (Vasconcellos and Cochrane). Each of the subsequent case studies describes techniques for managing both struggling and successful fisheries. These case studies focus on the development of new or developed fisheries that have limited data (Bechtol and Trowbridge; Bureau and Hand; Therriault et al.) and the recovery and management of struggling resources (Bargmann et al.; Kruse et al.; Stephenson and Jackson). Despite their geographically and species-specific nature, the general knowledge contributed by these case studies may be highly relevant to similar fisheries in data-limited situations in other parts of the world.

The second section focuses on developing indicators of stock health and productivity from limited data sets. Each paper describes a case study where early warning signs can be detected in order to predict the state of fisheries resources. The indicators that are described include biological indicators (LeBlanc et al.; Tribuzio et al.), performance indicators and stock dynamics (Hay et al.; Orensanz; Raid et al.; Ziegler et al.) and management indicators (Howland and Tallman; Scandol; Weyl et al.). A key paper from this section is a simulated study of Yellowfin Bream (*Acanthopagrus australis*) where empirical stock-status indicators were assessed using quality control methods (Scandol).

The third section focuses on the integration of local fishermen and traditional ecological knowledge in fisheries management. A key paper in this section by Freire describes the use of data provided by anglers in the assessment of Brazil's growing recreational fisheries industry. This paper represents the first data of their kind from South America and illustrates the potential value of recreational anglers as a key data source for improving fisheries management in data-limited situations. The fourth section contains papers that are geared towards the assessment of the effects of fisheries at the ecosystem level by using ecosystem indicators (Stobberup et al.) or models (Ainsworth and Pitcher; Cheung and Pitcher; Morato and Pitcher). This section contains an interesting study by Cheung and Pitcher that outlines possible strategies for evaluating fisheries management policies that aim to conserve biodiversity. The fifth section contains a number of studies that take a precautionary approach to data-limited fisheries management. The majority of the studies in this section focus on fisheries uncertainty (A'mar and Punt; Campbell and Dowling; Punt and Methot; Welch; Zheng). One key paper involves an evaluation of a multi-stage approach to data-limited fisheries management. Perry et al. assesses the four-stage approach to new and developing fisheries (i.e., data collection, design of key studies, implementation of selected strategies and establishment of the new fishery) designed by Fisheries and Oceans Canada. One of the most challenging factors in this staged framework, as with the management of many of the world's fisheries, is the contradiction between the demands of access to fisheries and the conservation of these resources. This paper addresses some key points that are relevant to balancing these challenges.

The sixth section contains several papers that address the use of models in stock assessment. Stock assessment bias and sensitivity are addressed by two key papers in this section (Ernst and Valero; Mesnil). Also, Catch-Survey Analysis (CSA) is discussed by two papers to estimate stock abundance (Collie et al.) and to address concerns over sensitivity and bias (Mesnil). Similarly, the seventh section addresses stock assessment methods and surveys. In this section, several key methods are described, including population density assessments using scuba (Byerly and Bechtol) and the applications of acoustical estimations (Kaljuste et al.). This section also addresses sampling designs for estimating bycatch (Menon et al.), methods for accounting for climate variability in models (Shotwell) and assessments to address concerns over recreational overharvesting (Therriault and Hay). A case study discussing the modeling of climate variability in relation to forecasting Pacific salmon spawner-recruit dynamics (Shotwell et al.) is particularly relevant to data-limited fisheries that require the input of variable environmental data into forecast models.

This book contains an excellent assemblage of well-written, highly relevant research papers on data-limited fisheries. Several management themes emerge from this book, including (1) the development of key rapid assessment tools, (2) the integration of traditional knowledge from fishermen and local ecological knowledge, (3) the adoption of a precautionary approach to fisheries management, (4) the evaluation of sensitivity and bias in stock assessment models, and (5) the development of robust stock assessment methods. These key strategies recur throughout many of these studies and are relevant to fisheries worldwide. Further, several novel strategies for managing data-limited fisheries are discussed, including the development of key modeling and assessment tools. This book offers one of the first attempts to assemble key literature on data-limited fisheries into a single volume. This is an invaluable resource for the management of new or developing fisheries.

The intention of this collection is to provide scientific background to new and developing fisheries. Each research paper attempts to suggest applications of their case study to other similar data-limited fisheries resources. However, the seven sections contained in the book are organized with little or no preface or interpretation of this research. Throughout the book, the links between the results of each case study to a broader application are often tenuous. For most proceedings books in this style, it is common to omit interpretations by the authors or editors in each section. However, the nature of this research demands a synopsis in each section to highlight the applications and extensions of this research. Managers require the interpretation of fisheries experts who are experienced with data-limited

situations to identify how the methods described in this book can be applied to their own data-limited situations. In summary, the management themes that emerge from this collection are highly relevant to all fisheries managers, policy makers and scientists working with data-limited fisheries. However, this book would be considerably more useful to these stakeholders if the context of each section was clearly described in a one to two page preface and synopsis summary that outlines how this knowledge could be applied in practice.

Lapland – A Natural History

By D. Redcliff. 2006. Yale University Press, P.O. Box 209040, New Haven, Connecticut 06520-9040. 352 pages, U.S. $60. Cloth.

Lapland: a Natural History by the late Derek Redcliff, is a remarkable account of the birds and higher plants of northern Scandinavia. This book begins with a general description in land use and the geological background terms followed by a skillful history of the earlier naturalist visitors. The book is mainly given over to a detailed evaluation of the various habitats found in this area. These include Boreal Forests, Forest Peatlands, Lakes and Rivers, Coastlands, Tundra and Man-influenced habitats. Each of these chapters is divided into vegetation and flora and birds. The birds section is subdivided into key groups such as wildfowl, waders (shorebirds), birds of prey, songbirds and birds that are of particular importance in that habitat (e.g., wildfowl or grouse).

The author writes in a style reminiscent of a professor giving a lecture to keen students and as a result the book is easy and pleasant to read. The accounts are packed with information drawn from many research sources, backed up by the author's own observations. The text does contain references, but not in sufficient number to impede the flow of ideas. Every few pages there are four half-page photos. These depict habitats, plants, birds and bird nests. Particularly impressive are the almost two dozen photos of shorebird nests (have you ever tried to find a shorebird nest?). These photos, most by the author, are of very fine quality. Interspersed with the text are some engaging black-and-white illustrations by Mike Unwin, reminiscent of those in the journal, *British Birds*.

I particularly enjoyed the way Redcliff linked the occurrence of a species with the other components of the habitat. He does a wonderful job of showing the inter-dependance of each constituent of a habitat and the consequences of disruptions to the balance, both natural and man-induced.

Even though I found this a treasure trove of information (and wisdom) I did have several problems. I hoped, while doing this review, I could compare the plant life of Northern Canada, Svalbard and Lapland. The author's inconsistent use of scientific names became a source of frustration for making this comparison. The worst case was his discussions of Dwarf Azalea. As he does not include the scientific name it is hard to be sure which plant he is referring to. Lapland Rosebay (Canada) or Lapland Rhododendron (Europe) is *Rhododendron lapponica*, but the author quotes this plant separately. Indeed, he includes a beautiful photo of this lovely plant. He also includes a photo of "Dwarf Azalea", but it is a very un-Rhododendron-like plant (more like a saxifrage or even Moss Campion). After much searching and consultation with Bill Cody (author of several books etc. on northern plants) I was still unclear until I found a reference to *Loiseleuria procumbens* as Trailing Azalea (and several other English names) while identifying plants from Cambridge Bay, Nunavut. Similarly I was never sure if the Finnmark Primrose was the same as *Primula erects* or *nutans* or if it was a new species or subspecies.

Also the book only covers the higher plants well. There is relatively scant mention of the lichens and other more primitive plants. I am sure that there must be well over 500 species of lichens in this area, yet the book refers to only a handful. Other groups are even more poorly represented. On the animal side, birds are well covered. Mammals get an introduction and other groups (reptiles, amphibians, butterflies and dragonflies) get an honourable mention. Other wildlife such as beetles and bugs do not get any attention.

I also had problems with many of Redcliff's terms. To start with, he does not really define what he means by Lapland, Fennoscandia, Fennoscandinavia and Scandinavia. As he uses terms like "Southern Lapland", I felt it important to understand the region's precise location. His map showing the location is vague so I thought I would check further. Lapland is somewhat well defined (northern Norway, Sweden, Finland and Russia – or the home of the Sami). Actually I have found Finnmark, Nordland, Nord-Trøndelag and Troms [counties of Norway], Lapland [a province of Finland], Jämtlands Län, Norrbottens Län and Västerbottens Län [counties of Sweden], and Murmansk [an oblast – or "province" – of Russia] form Lapland. Knowing at least where the county of Finnmark is located is most useful when reading the text. However, the other terms vary from source to source. They could include some or all of Norway, Sweden, Denmark, Finland, Iceland and the Faeroes. Similarly I had trouble with the terms flark, fell, strang, patterned fen and mire. Eventually I did get them sorted out but a glossary would have been so helpful.

I have several problems with the index. First, it does not reference any scientific names, only English ones. None of the photos are listed. Some of the entries are

listed forward (e.g., Lapland Rhododendron and Alpine Lady Fern) and some entries are listed backward (e.g., Primrose, Finnmark and Birch, Downy) making it difficult to decide which letter to use.

The author includes range maps from other sources. The maps for plants use the scientific names (If you did not know *Silene acaulis* is a Moss Campion [as opposed to the synonyms: *Silene bryoides, Silene exscapa*] you would be a little lost. The lovely photo of *Parmelia centrifuga* is not identified as a concentric ring lichen). The map captions for birds use English names. The maps are not in the index.

The Three-toed Woodpecker was split in 2003 into the American Three-toed (*Picoides dorsalis*) and Eurasian Three-toed woodpeckers (*Picoides tridactylus*) using differences in mitochondrial DNA sequences. The author has not mentioned this or any other recent splits. Perhaps this is not as significant a issue in a book focused on ecology rather than identification.

Finally, the book contains two photos of people; one is the author, although the caption omits this detail and the other is Jeanette. The book is dedicated to this lady, but her presence is never explained (she is Mrs. Redcliff).

This is a great book for anyone interested in the far north or who wants to understand the complexities of life. It is wonderful and fascinating reading if you are passionate about natural history, but is of more limited value for research.

Derek Redcliffe was the first to establish the role of agricultural pesticides with the decline of birds of prey. He was chief scientist of the Nature Conservancy Council in the UK where he acted as a scientist and lobbyist for nature conservation. He fearlessly attacked and changed agricultural and forestry interests for the damage to wildlife value caused by their policies and practices in place at the time. Not an easy or popular task in Maggie Thatcher's world. Despite his legendary contribution to UK conservation he was denied any honour by the state – in a country that knights pop stars. Redcliff was known an extraordinary naturalist, good company and friend. His last book is a fitting legacy.

2193 Emard Crescent, Beacon Hill North, Ottawa, Ontario K1J 6K5 Canada

Fish, Fur and Feathers: Fish and Wildlife Conservation in Alberta, 1905-2005

Fish and Wildlife Historical Society. Federation of Alberta Naturalists (FAN), Edmonton. $39.50, 418 pages.

This sumptuous, well-illustrated book is an eclectic mix of articles, reminiscences and interviews. The main text is on white paper, and the other contributions on yellowish paper. Only rarely does this confuse the reader but the white paper portion of chapter four ends in the middle of an incomplete sentence.

As expected with any product of a committee, some chapters are stronger than others. We often know who wrote a particular piece, but sometimes we don't. Nowhere, not even at the end of the two-page Editor's Note, are we told the name of the chief editor (Bill Wishart, as I learned from a special enquiry to Edmonton). At the end of each chapter are references and a useful chronological list of the main happenings.

In Alberta, as elsewhere, the responsibility for fish and wildlife management grew from a handful of voluntary game guardians to a diverse group of biologists and enforcement officers within professional, academic, and conservation communities. Yet for the better part of a century the emphasis was on fishing and hunting. In 1967 the first female biologist (now the president of the Canadian Medical Association) was hired, and only in 1987 was the first non-game biologist hired. Now there are 14 recovery teams developing and implementing plans for threatened and endangered species.

Some accounts are superb. The account of the change in upland game numbers associated with harvesting practices, from threshing machines, grain separators, and wheat stooks to combine harvesters, is among the best I have encountered.

Alberta has had some unique successes. The Peregrine Falcon restoration program, under the direction of Richard Fyfe, was immensely important. One week in the 1960s, biologists taught a three- or four-evening short course in wildlife biology and management, specially designed for Members of the Legislative Assembly; more than half of them attended! A M.Sc. thesis on the fish and wildlife damage inherent in the planned Highwood Dam helped to influence the shelving of that project.

Biographical information is generally excellent, giving credit to world leaders in biology, especially William Rowan. Even though this book is co-sponsored by the FAN, amateurs are somewhat slighted, except for Frank Farley, Cam and Joy Finlay, Elsie McAllister, Myrna Pearman, Dewey Soper, and Kerry Wood. Edgar Jones is barely mentioned and Otto Höhn, Robert Lister and Al Oeming are omitted. Information resulting from bird banding is provided only as regards waterfowl. The Beaverhills Bird Observatory is not indexed. The outstanding studies of Golden Eagle migration west of Calgary by Peter Sherrington, the landmark studies of Ferruginous Hawk biology by Josef Schmutz, and the northern owl banding by the Edmonton group are not mentioned.

The compilers are frank about some of the bureaucratic bungles ("bureaucracies are often much too shortsighted," page 207) and failures, such as legislation

drafted, but never proclaimed. The "biggest mistakes of the century" are identified as the transfer of diseased bison to Wood Buffalo Park, game farming, predator control attempts, "too many fishermen," and loss of habitat.

There are a few errors of fact and interpretation. The two-page account of the Prairie Farm Rehabilitation Administration is unusually misleading when it speaks of 87 community pastures by 1999, omitting the fact that only one (in three blocks within the Suffield Military Range) of these PFRA pastures is in Alberta. The American White Pelican was threatened, never endangered (page 341). Gary Pelchat was born in Ponteix, not the never-existent Phoenix, Saskatchewan. David Munro is misspelled "Munroe". The first two Franklin Arctic expeditions were hoping to find an arctic sea route, not an overland route to Asia. The index is inadequate, failing to index names of any organism (e.g., pronghorn, ring-necked pheasant, and liver fluke). For consistency, the book title might better have been *Fin, Fur and Feathers*.

With pressure from an increasing urban human population, highways, and mechanization of farming, mining, oil extraction, forestry, dams and irrigation, it will be difficult to maintain biodiversity in the decades to come. Some hope may be gained from looking at both the successes and failures of the past.

A large book, it is too heavy for bedside reading. Caveats aside, this is a wonderful collection of information that should be in all major Canadian libraries, and read by everyone interested in the history of fish and wildlife conservation and management.

C. STUART HOUSTON

863 University Drive, Saskatoon, Saskatchewan S7N 0J8 Canada

The Gulf of Alaska: Biology and Oceanography

By P. Mundy 2005. Alaska Sea Grant College Program, University of Alaska-Fairbanks, Edited by Exxon Valdez Oil Spill Trustee Council.

Alaska is perceived "...as a place of wilderness, beauty and a special way of life". This book describes the Gulf of Alaska (GOA), a region with many world records. Besides covering a huge area, having the third largest permanent ice field in the world and being a central place, crossroads, for almost all of the Pacific salmon, GOA also is among the most productive oceans in the world.

The introduction is a chapter on general oceanography for the lay public; the classic concept of the 'Conveyor Belt' is presented. Due to its ecological importance, I like the human footprint statement such as "Human uses of the GOA are extensive" and "... it is rare to walk the intertidal zone anywhere in GOA without seeing evidence of human activity". The "...marine pollution and floating refuse from as far away as Asia, or originating from deliberate deep-ocean dumping or accidents at sea, can be swept north and westward around the shelf edge in the GOA. Trash from the international fishing industry operating 200 miles offshore is commonly found on beaches". Further, one will read that GOA has arguably the best known rocky tidal zone on earth, and this small tidal zone is crucial for the ocean. This book admits climate change but leaves it somewhat undefined whether it is a man-made issue, or not.

The book contributors emphasize that to fully understand the ecology of GOA first one needs to make an effort to identify of all relevant species, e.g., plankton. Shrimp, once among the dominant benthic epifauna in Lower Cook Inlet, Kodiak and along the Alaskan Peninsula, declined after maximum harvests in 1977, and today its fishery is virtually nonexistent. Red King Crab crashed in 1980, and Tanner Crab fisheries are down as well. The clam fishery in Cordova never recovered from damages brought by an earthquake. Despite its fishery of global importance, the two short paragraphs for the Pacific Cod section are rather uninformative. The fisheries for Walleye Pollock have been down since 1982. The Herring loss story for Seldovia Bay and Lower Cook Inlet is reported on as well. Salmon from Japan, Russia, British Columbia, all of Alaska and the Pacific North West spend some part of their life cycle in the GOA. The canned salmon industry collapsed in 1959, the year when Alaska became a U.S. state.

Despite all of this overwhelming evidences of limited ocean supplies, some book contributors still claim in their chapters the traditional views of "unlimited resources". Other sections blame the "stocks" and anglers for their impacts (rather than their managers with a governmental mandate for safeguarding the public resource). Fortunately, sea floor dredging effects are explained, since fishery impacts to the soft-bottom benthic community are a possible driver of community change. It is suggested in the book text that this affects Steller Sea Lions as well.

Throughout, the book shows that for non-commercial species we lack management information. These species compose the bulk of the biomass. By-catch of the juvenile cohort occurs in fisheries like Herring, Pollock, and Salmon. However, for many of the non-commercial species the magnitude of this phenomenon is not really known, nor how much it affects these stocks.

Even apart from all of these severe marine issues mentioned in the book, the described terrestrial situation is equally puzzling: The book states that in the GOA, 24% of the water bodies listed are on the state's list of polluted sites attributed to some aspect of logging.

The book makes clear that Alaskan "Subsistence Harvest" is a much-debated issue, a major political player in Alaska and beyond, and thus, well supported by the government. However, only 2200 people in the Exxon Valdez Oil Spill (EVOS) region actually still practice this form of life style. This must be among the most subsidized lifestyles in the world. The government uses undercover agents to report on how much natural resources are taken.

How much do Alaskans value their nature? This book provides an answer: Anchorage operates under a Clean Water Act Section waiver, only completing primary treatment of the sewage. The classic cocktail of PCB, DDE, DDT and Dioxin gets named several times, but there are many more pollutants in the Arctic. The complex toxic pollution of the Copper River is mentioned though. I think that most readers will get excited that the Alaskan government does not choose to monitor for environmental pollutants.

A seabird chapter deals with nesting species, not with its pelagic, non-breeding populations. Cliff nesting murres and Black Kittiwakes are the most well studied; underground and nocturnal species are hardly known. The statements "There is no evidence that seabirds in the GOA have been directly affected by commercial fisheries" and " ...do not compete with commercial fisheries for biomass" give the wrong impression. The book publishers need to be chastised for this misleading statement as it sets the stage for inappropriate environmental management policies in favour of economic activities.

Seabird starvations in GOA are mentioned several times; e.g., related to climatic ENSO (El Niño/Southern Oscillation) events. There is nice documentation of increased gull predation e.g., Glaucous-winged Gulls on Black-legged Kittiwakes, due to increased gull populations. The given Marbled Murrelet estimate of 200 000 nesting birds is likely low when compared with the authoritative literature. The provided nesting seabird population table is misleading since non-breeders occur in the region and thus, populations are higher.

The Minerals Management Services, EVOS, NMFS (National Marine Fisheries Service), and the Alyeska Consortium did extensive benthos survey and monitoring efforts in GOA in the 1970s. The reader is left wondering where these raw data are and this book does not help us to learn where to find them. One simply has to trust the "experts" blindly. This must set the stage for conflict.

The contaminant issue I find not well handled in this book either, considering that EVOS was a GOA event of global attention and recognition. Since this book is an EVOS publication one has to ask, what did we really learn from EVOS? There is no chapter devoted to toxicology or sections contributed by a professional Alaskan toxicologist. One will have a hard time to find much oil spill literature. At least we know, in 2000, 604 spills were reported in the EVOS GOA region alone, proving we do have an oil and hazardous substances problem.

The book notes that there is a conflict between increasing development and loss of environmental quality in the GOA region (as found anywhere else in the world). Rats, ground squirrels and voles introduced in most of the Aleutians between 1700 and the 1900s make for a great example. Other examples include fox farms starting 1894 onwards, followed by canneries, the Klondike Goldrush of 1897, a copper mine operated from 1905 and the Northwestern railway built in 1911.

Marine mammals are elaborated on in greater detail: seal decline in 1973-2000 and the sea lion decline of approximately 83% (maybe >90%). The federal funding for investigating this sea lion decline is between 40 to 60 Million $$; a record in federal spending on one species. Was it a success?

The infamous Killer Whale story and their blame for the seal decline gets featured as well; e.g., in Prince William Sound, Killer Whales consume 400 seals each year (somebody has to eat the individuals of poor health; sharks were suggested as well). Killer Whales are believed to have suffered through EVOS.

Ecologists might be happy to see that the textbook example of how Sea Otters and their over-harvest links with Sea Urchin and kelp populations is mentioned. The book reports that lead in Sea Otters can now be traced directly to industrial sources, namely from North America and Asia, which makes for a great example for the need of international management in GOA (none of this is demanded in the book text though).

Overall, it remains unclear to me what the exact focus of this book is, and why it was published. Readers must see it as a major oversight that no professional contacts and addresses are provided for the 13 contributors or even editors. I found the content editing sometimes poor and not well structured. This becomes obvious in the multiple mentioning of the study area and its repetitive definitions and maps throughout chapters. Some of the chapter sub-headings are virtually similar to the chapter heading, other sub-headings and themes re-occur in other chapters. The quality and amount of citations varies throughout chapters. I like the abbreviation and acronym section because it also includes websites and their URLs. Some of the figures are stunningly made, but unfortunately in black and white.

It becomes quickly obvious that in concert with the many other signs and evidences there is something wrong with the natural state of GOA, and subsequently how it is managed. This book is a great example how unpublished and non-peer reviewed grey literature can rather add to confusion and is not achieving its goals for sustainable management.

Fossil Legends of the First Americans

By Adrienne Mayor. 2005 Princeton University Press, Princeton, New Jersey, USA. 446 pages. illustrated.

The lure of fossils is not a recent venture. For centuries, by accident or pursuit, "sports of nature" as they once were called have fascinated our cultures. Yet, while fossils rose from "sports" to conceptions of the organic past, this was essentially a western perspective, shaped by culture and scientific advancements. It is a little surprise, however, that the North American aboriginals or First Nations people were also drawn to these pieces of the past. The reasons varied, to be sure, but hidden to us were concepts of evolution and a sense of deep time. It is a great fortune that author Adrienne Mayor has investigated and recorded this diversity of cultures, much of it based on the oral, not written, tradition, and to some extent existing in various artifacts.

Mayor's first foray into fossil lore and history was *The First Fossils Hunters, Paleontology in Greek and Roman Times* (2000) which examined Greek and Roman period and place with respect to fossils. Of course these cultures are rich in textual artifacts and documentation, and were in essence at the root of western civilization. Mayor's recent study, *Fossil Legends of the First Americans*, is somewhat more of a challenge. As part of paleontological lore, aboriginal communities certainly had contact with fossils but to what extent? Lacking written tradition, painted in broad strokes, and compounded by our interpretation of their awareness, what were their concepts of "deep time", extinction, or even a notion of evolution?

Mayor argues that aboriginals had more than a cursory view of fossils, and in many respects, and with a much finer, multi-colored strokes particular to specific groups, their views are much richer than anyone expected. By reviewing cultures from south to north, each North American culture ebbed and flowed territorially, originating or modifying concepts of their surroundings and to some degree of the fossil bones and stones encountered. Some Navajos in the southwest United States, for example, believe that it is horrific to disturb buried bones. "The Navajos envisioned a series of past worlds that were destroyed before this world" says Mayor, each with good and evil monsters. By digging them up, the fear emerges of bringing these past monsters to our world. The large fossils found in the Navajo territory bespeak of life of great size in the form of petrified logs from the Petrified Forest National Park in Arizona, and of other possibilities in the rich, paleontological nest that they could have come across. This is more than mere tales of monsters.

Fossils were not always considered dire by those who came across them. "Rock medicine of the Crows and their traditional enemies, the Sioux, often included unusual fossils, especially ammonites and baculites" (page 268). They believed that these fossils carried with them mystical powers. In Alberta, medicine pouches of the Blackfeet often carried "buffalo-calling stones", which are the segmented portions of a Cretaceous baculite that look the shape, in cross section, of a buffalo. Aboriginals even attach some significance to the esthetics of fossil-bearing rock, in one case a point made of Pennsylvanian-age rock containing the ornate designs of the single- celled marine fusulinids from Kansas.

Throughout Mayor's work she references the revered paleontologist the late George Gaylord Simpson (1902-1984). Like the few earlier records of ethnology and paleontology, Simpson is often taken to task for his forays into the history of fossil collecting in North America. His definition of "discovery" was much narrower than Mayor's. He believed that "merely seeing a fossil bone or picking up an idle curiosity is hardly discovery" (1943, page 26). Therefore, Simpson gave little weight to beliefs and customs of First Nations people with regard to fossils in his reviews. He knew that there was contact with fossils, as in the case with the abundant fossils from the "Big Bone Lick" of the Ohio Valley, popular in the lore of American history as well as paleontology, but that's about it. Despite the fact that Simpson's views were reflective of 1940s American culture, Mayor's stance is that the discoveries "were not scientific in the modern sense, of course, but there is something akin to scientific inquiry in these activities" (page 29-30). Many of the aboriginal oral traditions were handed down from one generation to another, thus becoming a permanent record in their culture. This is one of the requisites of scientific tradition.

The 19th century American expansionism included vast paleontological initiatives like those seeded by Joseph Leidy (1823-1891), O. C. Marsh (1831-1899), and E. D. Cope (1840-1897). Ethnological initiatives also followed, but for some reason, cultural interpretation and fossils never met. Even when aboriginals were hired as scouts for the paleontologists, the "paleontologists ... [left] folklore to the ethnologists, so the ethnologists left paleontological topics out of their conversations with Native Americans" (page 195). As such, paleontological/ethnological information gathered today, some if recorded for the first time by Mayor, is tainted with over a 150 years of invading culture. A number of these aboriginal cultures have substituted their original, monstrous, interpretations of fossils with post-1840s terminology like "dinosaurs".

Where Mayor falls short, however, is in the extent of parallelism between aboriginal and western views of fossils and their meaning. There are a lot of "may have[s]", "could appear[s]" between the two views of scientific and cultural interpretation, and thus some of the interpretations seem somewhat forced. For example, an Assinoboine tale has "a great river monster" succumbing to a "violent death by the impact of a

"thunder stone", a black projectile that came whistling out of the west" at great speed and sound, "*a scenario that seems akin to the modern theory of an asteroid impact 65 million years ago*" (page 289; emphasis added). The implied connection is not tenable. Likely an interpretation of a meteor, the connection between the extinction of a group of species by an extraterrestrial object is a contemporary idea.

Fossil Legends of North American should have been written a century ago when contact with the First Nations people was still fresh. But the exploration of the cultural/science intertwining is still a relatively recent phenomenon. In this case, only a few other recent titles address fossils in a cultural context (see Cohen 2002; and to a lesser extent Semonin 2000). Still, if it were not for Mayor's effort, from documenting the oral traditions, the searching of archives, museums and journals, we would be left with a culturally insensitive, simpleton view of rich and diverse cultures and their varied, unique surroundings.

TIM TOKARYK

Box 163, Eastend, Saskatchewan S0N 0T0 Canada

A Field Guide to Gold, Gemstones & Mineral Sites of British Columbia, Sites Within a Day's Drive of Vancouver

By Rick Hudson, 2006. Volume 2 Revised Edition. Harbour Publishing Co. Ltd., P.O. Box 219, Madeira Park, British Columbia VON 2H0 Canada. 368 pages $26.95 Paper.

Rick Hudson has succeeded in expressing his passion for mineral collecting through his field guide book. On a second level he also tries to promote a sense of adventure by teasing the reader to go out and explore or prospect for nature's buried treasures.

The author structured the book so the reader can easily cross-reference required information in the lengthy location lists. A "How to use this Book" and a "Quick Reference Guide" helps to quickly locate items of interest throughout the book.

The book cover illustrates the hobby of mineral collecting as a family activity. Hudson educates the reader from first principles on how to become a rockhound. To accomplish this, he describes how to prepare yourself by choosing proper clothing, safety gear, collecting tools and maps. He warns the future mineral collector about natural hazards they may encounter such as rattlesnakes, grizzly bears and ticks. Ethics, access rights and mineral rights are also discussed to keep the collector within acceptable collecting practices and to avoid unintentional trespassing.

Mineral collecting is attractive to many people because as you find an interesting mineral specimen, you want to learn how nature created it and or its geological history. The author has included short geological descriptions partitioned by collecting areas as well as mining histories of local economic importance within the collecting area.

Colour plates illustrate the minerals found in some of the collecting sites and detailed occurrence maps are included in all the collecting area sections throughout the book. The colour plates represent minerals that are possible to find in the collecting sites. Government mineral index files were included in the locality information along with detailed road log descriptions.

The author has made a successful merger of personal knowledge and technical data to compile an informative volume which can provide years of enjoyment for many future rockhounds and their families and friends.

Marine Turtle Newsletter (111)

January 2006. 28 pages: EDITORIAL: Does the Mediterranean Green Turtle exist? (N. Mrosovsky) — Comment on the guest editorial by Paul J. Ferraro (P.C.H. Pritchard) — Response to Comment by Peter C. H. Pritchard (P. J. Ferraro — ARTICLES: Report on long-term transmitter harness retention by a Leatherback Turtle (S. Dowling, R. Solano, A. Diaz-Merry, J. Ordonez, J. Taylor, D. R. Evans, D. Godfrey, D. Bagley, L. Ehrhart, and S. Eckert — Marine Turtles on the Southern Coast of Bioko Island (Gulf of Guinea, Africa), 2001-2005 (H. Rader, M. A. E. Mba, W. Morra, and G. Hearn — Incidental capture of marine turtles in Marine fisheries of southern Spain (J. C. Baez, J. A. Camidax, and L. Rueda — First evidence of Leatherback movement from Africa to South America (A. Billes, J. Fretey B. Verhage, B. Huijbregts, B. Giffoni, L. Prosdocimi, D. A. Albareda, J.-Y Georges, and M. Tiwari — NOTES: *Charybdlis hellerii*, a non-indigenous portunid crab from the gastrointestinal contents of a Kemp's Ridley Sea Turtle (*Lepidochelys Kempi*) in Georgia, USA (M. Frick and K. Williams) — An update on Eritrea's marine turtle programme and first record of Olive Ridley turtle nesting in the Red Sea (n. Pilcher, S. Mahmud, S. Howe, Y. Teclemariam, S. Weldeyohannes, T.Menggsu, and M. Giotom — Epibionts associated with *Chelonia mydas* from northern Brazil (S. Pereira, E. H. S. M. Lima. L. Ernesto, H. Mathews, and A. Ventura — Small Leatherback found in Dominica (R. Byrne and S. A. Eckert) —MTSG UPDATE — ANNOUNCEMENTS — NEWS & LEGAL BRIEFS — RECENT PUBLICATIONS.

The Marine Turtle Newsletter is edited by Brendan J. Godley and Annette C. Broderick, Marine Turtle Research Group, Centre for Ecology and Conservation, University of Exeter in Cornwall, Tremough Campus, Penryn TR10 9EZ United Kingdom; e-mail MTN@seaturtle.org; Fax +44 1392 263700. Subscriptions and donations towards the production of the MTN can be made online at <http://www.seaturtle.org/mtn/> or postal mail to Michael Coyne (online Editor) Marine Turtle Newsletter, 1 Southampton Place, Durham, North Carolina 27705 USA (e-mail: mcoyne@seaturtle.org).

Wildlife Afield 2(1,2)

A British Columbia semi-annual publication (ISSN 1712-2880) published by The Biodiversity Centre for Wildlife Studies twice a year. Additional information at www.wildlifebc.org.

Volume 2, Number 1, contains FROM THE EDITOR: Spinning a web — On the covers — FEATURE ARTICLES: Migratory occurrence and status of select shorebirds in the vicinity of Fort St. John, British Columbia (Chris Siddle) — Survey of Painted Turtles in the Creston Valley, British Columbia, in 2003 and 2004 (Linda M.Van Damme) — NOTES: Changing status of Ring-necked Ducks wintering on Salt Spring Island, British Columbia, 1978-2004 (Robert B. Weeden — Barred Owl feeds on Ban-tailed Pigeon (David C. Schultz) — First winter occurrences of the Cape May Warbler for British Columbia (Phil Ranson) — Burdock entrapment of a Ruby-crowned Kinglet in the Creston Valley — First nest and eggs the Canada Warbler for British Columbia (R. Wayne Campbell) — Pinyon Jay (*Gymnorhinus cyanocephalus*): A new species for British Columbia (Kim Asquith and Malcolm Dennington) — Incidences of Gopher Snake predation in bluebird nest boxes — Unsuccessful nesting attempt of Black-necked Stilt in British Columbia (Ryan Tomlinson) — Status of the Rock Pigeon (*Columba livia*) in Nelson, British Columbia (Janice E. Arndt) — WILDLIFE DATA CENTRE: Featured species — Thinhorn Sheep (Fred L. Bunnell) — Report of the Wildlife Data Centre: 1 January 2005 to 30 June 2005 (Michael I. Preston) — BRITISH COLUMBIA ROUND-UP: News of Friends — From the Archives — Final Flight — Publications of Interest (Compiled and edited by Chris Siddle) — Announcements and Meetings.

Volume 2, Number 2, contains: FROM THE EDITOR: A turn of the times —On the covers — FEATURE ARTICLES: Field Survey of Red-eared Sliders (*Trachemys scripta elegans*) in the Lower Fraser Valley, British Columbia, in 2005 (Cory G. Bunnell — Origin and current status of the Pacific Pond Turtle (*Actinemys marmorata*) in British Columbia Francis R. Cook, R. Wayne Campbell and Glenn R. Ryder — Recent range expansion of Sandhill Cranes (*Grus canadensus tabida*) in southeastern British Columbia (Doug -

las Leighton — Diet of Great Horned Owl in the Creston Valley, British Columbia, 1998-2005 (Linda M. Van Damme — NOTES: Anti-predator behaviour by a Mule Deer to Coyotes in Vernon, British Columbia (Chris Siddle) — Attempted capture of a Red-legged Frog by an American Robin (Michael I. Preston) — Evidence of an unusual prey item in a Barred Owl pellet (Christian W. Gronau) — Northernmost nest record of the Flammulated Owl (*Otus flammeolus*) in Canada (Karen L. Wiebe — First nesting record of Say's Phoebe (*Sayornis saya*) in the East Kootenay, British Columbia (Robert S. Ferguson and Mark Dascher) — Current status of the Black-throated Blue Warbler in British Columbia (Gary S. Davidson — Field observations of Gray Flycatchers breeding at Summerland, British Columbia, 1988-2005 (I. Laurie Rockwell) — American Crow predation in an Eared Grebe nesting colony at Rawlings Lake, British Columbia (Chris Siddle) SPECIES OF REGIONAL SIGNIFICANCE: Canvasback Fort St. John (Chris Siddle) — Bobolink — Nakusp to Edgewood (Gary S. Davidson) — WILDLIFE DATA CENTRE: Featured species — Turkey Vulture (R. Wayne Campbell, Michael I. Preston, Linda M. Van Damme, and Diann MacRae — BRITISH COLUMBIA ROUND-UP: Field notes and caring people — News of Friends — From the archives — Final flight — Publications of interest [Compiled and edited by Chris Siddle] — Announcements and meetings.

Advice for Contributors to *The Canadian Field-Naturalist*

Content

The Canadian Field-Naturalist is a medium for the publication of scientific papers by amateur and professional naturalists or field-biologists reporting observations and results of investigations in any field of natural history provided that they are original, significant, and relevant to Canada. All readers and other potential contributors are invited to submit for consideration their manuscripts meeting these criteria. The journal also publishes natural history news and comment items if judged by the Editor to be of interest to readers and subscribers, and book reviews. Please correspond with the Book Review Editor concerning suitability of manuscripts for this section. For further information consult: A Publication Policy for the Ottawa Field-Naturalists' Club, 1983. *The Canadian Field-Naturalist* 97(2): 231-234. Potential contributors who are neither members of *The Ottawa Field-Naturalists' Club* nor subscribers to *The Canadian Field-Naturalist* are encouraged to support the journal by becoming either members or subscribers.

Manuscripts

Please submit, **to the Editor,** in either English or French, **three** complete manuscripts **written in the journal style.** The research reported should be original. It is recommended that authors ask qualified persons to appraise the paper before it is submitted. All authors should have read and approved it. Institutional or contract approval for the publication of the data must have been obtained by the authors. Also authors are expected to have complied with all pertinent legislation regarding the study, disturbance, or collection of animals, plants or minerals. The place where voucher specimens have been deposited, and their catalogue numbers, should be given. Latitude and longitude should be included for all individual localities where collections or observations have been made.

Print the manuscript on standard-size paper, **doublespace throughout,** leave generous margins to allow for copy marking, and **number each page.** For Articles and Notes provide a bibliographic strip, an abstract and a list of key words. Generally, words should not be abbreviated but use SI symbols for units of measure. The names of authors of scientific names may be omitted except in taxonomic manuscripts or other papers involving nomenclatural problems. "Standard" common names (with initial letters capitalized) should be used at least once for all species of higher animals and plants; all should also be identified by scientific name.

The names of journals in the Literature Cited should be written out in full. Unpublished reports and web documents should not be cited here but placed in the text or in a separate Documents Cited section. List the captions for figures numbered in arabic numerals and typed together on a separate page. Present the tables each titled, numbered consecutively in arabic numerals, and placed on a separate page. Mark in the margin of the text the places for the figures and tables.

Check recent issues (particularly Literature Cited) for journal format. Either "British" or "American" spellings are acceptable in English but should be consistent within one manuscript. **The Oxford English Dictionary, Webster's New International Dictionary** and le **Grand Larousse Encyclopédique** are the authorities for spelling.

Illustrations

Photographs should have a glossy finish and show sharp contrasts. Electronic versions should be high resolution. Photographic reproduction of line drawings, **no larger than a standard page,** are preferable to large originals. Prepare line drawings with India ink on good quality paper and letter (don't type) descriptive matter. Write author's name, title of paper, and figure number on the lower left corner or on the back of each illustration.

Reviewing Policy

Manuscripts submitted to *The Canadian Field-Naturalist* are normally sent for evaluation to an Associate Editor (who reviews it or asks another qualified person to do so), and at least one other reviewer, who is a specialist in the field, chosen by the Editor. Authors are encouraged to suggest names of suitable referees. Reviewers are asked to give a general appraisal of the manuscript followed by specific comments and constructive recommendations. Almost all manuscripts accepted for publication have undergone revision—sometimes extensive revision and reappraisal. **The Editor makes the final decision** on whether a manuscript is acceptable for publication, and in so doing aims to maintain the scientific quality, content, overall high standards and consistency of style, of the joumal.

Special Charges — Please take note

Authors **must share in the cost of publication** by paying $80 for each page, plus $15 for each illustration (any size up to a full page), and up to $80 per page for tables (depending on size). Authors may also be charged for their changes in proofs. Reproduction of color photos is extremely expensive; price quotations may be obtained from the Business Manager. If grant or institutional funds are not available, club members and subscribers may apply for a waiver of charges for the first five pages.

Limited joumal funds are available to help offset publication charges to authors with minimal financial resources. Requests for financial assistance should be made to the Editor when the manuscript is accepted.

Reprints

An order form for the purchase of reprints or PDF will accompany the galley proofs sent to the authors, and an invoice will be sent after publication. Payment should be by cheque or money order paid when the invoice is received.

The Canadian Field-Naturalist

Volume 120, Number 2 April–June 2006

A Tribute to George Wayne Douglas 1938 – 2005

JENIFER L. PENNY[1]

[1]Conservation Data Centre, British Columbia Ministry of Environment, Ecosystems Branch, P.O. Box 9993 Stn Prov Govt, Victoria, British Columbia V8W 9R7 Canada.

Penny, Jenifer L. 2006. A tribute to George Wayne Douglas 1938–2005. Canadian Field-Naturalist 120(2): 135–146.

Coming from humble beginnings, George Wayne Douglas, with his determination and strong spirit, established himself as one of British Columbia's most respected botanists. I first met George in 1995 when I began working with him at the British Columbia Conservation Data Centre (CDC). In time, I came to know him as an adept field botanist, a knowledgeable ecologist, an accomplished author, a practical taxonomist, a cunning businessman, a conservationist at heart, and a generous mentor. During our numerous field trips, George often talked about writing his memoirs and enjoyed recounting the stories and adventures that would go into the chapters. He had a lot of different experiences throughout his life that would have resulted in an interesting read. He was a born leader: he had a strong character, held his ground on issues, and had a critical, but practical approach. George had a vision for botany in British Columbia and he brought that vision to fruition.

George (known to family and close friends as Wayne) was born in the Royal Columbian hospital in New Westminster on 22 June 1938. He spent his early years exploring the bushes around the base of Burnaby Mountain near Vancouver, British Columbia, this may have been the root of his inspiration to study botany and ecology later in his life. He grew up in a large family with six brothers and sisters: Bonnie, Marilyn, and David who currently live in British Columbia, and Robert, who lives in South Africa (siblings David Charles and Judy predeceased him). His family was not affluent, so George always aspired to do well for himself, which he certainly accomplished.

As a youth, he excelled at sports but wasn't that interested in academics. In high school (Figure 1), he ran record sprints and was an excellent basketball player, as well as an accomplished golfer. He would continue to enjoy golfing throughout his life, playing at least two to three times a week. When he first started, at about 12 years of age, he used to sneak onto the Vancouver Golf Course, and golf his way to school, hide his clubs and then golf his way home after school. Later he was on the high school golfing team and was an amateur champion. He always knew how to have fun, especially back in high school, but he also worked hard. One of his favourite jobs at that time was at Labatt's Brewery where his Friday afternoons were spent "sampling" the products.

FIGURE 1. George at Como Lake High School (circa 1956).

Despite his lack of interest in scholarly pursuits in high school, George ended up at the University of Washington (College of Forest Resources) in Seattle, Washington, on a track and field, basketball and golf scholarship. George continued to work on his athletics; however, much to his surprise, he became very keen on his studies and excelled in his field. Although he never finished high school, during his educational career he ended up receiving three post-graduate degrees!

George had a scholarship but he still had to work part-time jobs to finance going to university. Amongst his occupations were working in a mill, a cannery and a slaughterhouse. He was also an ambulance and taxi driver. Later in his schooling he got work that better suited his career goals like as a forestry consultant, where he supervised forest inventory, mapping and reforestation projects. He also worked as an ecological consultant while attending University of Washington and completed inventories in the North Cascades National Park focussing not only vegetation, but also wildlife, soils and geology.

During his bachelor studies, George received tutelage from two famous Pacific Northwest botanists, Dr. C. Leo Hitchcock and Dr. Art Kruckeberg. In later years, George dedicated one of his books to Dr. Kruckeberg (*Mountain Plants of the Pacific Northwest*), in which he wrote that Dr. Kruckeberg had inspired him during his first plant identification attempts and started him on the road to his lifelong career in botany. Somehow, George even ended up getting bestowed with Dr. Hitchcock's plant press, a true honour for a botanist! As a result of considerable effort during his bachelor degree, he was accepted into graduate school and studied under Dr. Ronald J. Taylor. George received a Bachelor of Science degree in forestry in 1968 and a Master's of Science degree in 1970 from University of Washington.

George's master's thesis involved a vegetation study in the subalpine zone of the western North Cascades, Washington, which was published in *Arctic and Alpine Research* (Douglas 1970). Following his Master's degree, he moved back to Canada to embark on his Ph.D. at the University of Alberta (Department of Botany) in Edmonton, Alberta, with Dr. Larry Bliss. It was a good time to return to Canada since the United States Army was rallying young troops for Vietnam. His doctorate was a study of alpine and high subalpine plant communities of the North Cascades Range, in Washington and British Columbia, and he published the research in *Ecological Monographs* (Douglas and Bliss 1977). In 1974, following his doctorate at University of Alberta, he received a Postdoctoral Fellowship in the Department of Botany to study lichens of the North Cascade Ranges of Washington (Douglas 1974).

His graduate work took him to the places he loved – the mountains of the Cascade Range. In fact, there is a special place on Mount Baker called Grouse Ridge where he wanted to have his ashes spread, but alternatively he thought that Mount Prevost overlooking his home in Duncan would be a fine place too, which is where his family ultimately scattered his ashes.

After finishing his graduate studies, George took courses in landscape architecture at Pennsylvania State University, which later enhanced his immense enjoyment of gardening at home, but at the time, made him more marketable as a consultant. Then he focussed entirely on developing his consulting firm, Douglas Ecological Consultants Ltd., based out of Victoria, British Columbia. His consulting work was to take him all over British Columbia and to the Yukon Territory and resulted in valuable vegetation interpretations and guidance to land managers on the issues of environmental impacts and biodiversity monitoring.

In 1973 and 1974, he started working in the Yukon Territory, where the alpine was full of new species and breath-taking landscapes. His time there began when he was contracted by the Canadian Wildlife Service to examine the vegetation and soils of Kluane National Park and their vulnerability to land use within the park. George ended up spending eight summers working in the park, a good time for the business, but also some of the best memories of his life.

Parks Canada also hired him to work on many important projects in the 1970s. In fact, he was awarded some of Parks Canada's largest contracts ever. During this time he employed numerous prestigious scientists and colleagues to provide expertise on his projects. Among other projects, he was asked to evaluate the use and ecological impacts of chemical fire retardants in North America and to make recommendations on their future use, to assess the environmental impact of recreational use (mainly human and horse trampling) on different vegetation types in Waterton Lakes National Park, Alberta, and to assess the environmental impact of five potential transportation corridors in Kluane National Park. He also carried out a four-year biophysical inventory project in Kluane National Park, which was a multidisciplinary study that included ten professional scientists and reported on landforms, surficial deposits, soils and vegetation.

Douglas Ecological Consultants also worked on projects involving vegetation reconnaissance of large tracts of land in British Columbia, examining spruce hybridization in the province, evaluating the British Columbia ecological reserve system, air quality monitoring projects using lichens in northern Alberta, and a variety of environmental impact studies.

In the early 1980s, George started working on contracts for the British Columbia Ministry of Environment (MOE), for which he would work until his retirement in 2002. He started out at MOE as a consultant, designing and coordinating a biological monitoring network using lichens in northeastern British Columbia. He also investigated the occurrence of alpine plant communities in British Columbia for the Ecological Reserves unit of MOE, and suggested where new ecological reserves should be established.

FIGURE 2. George (left) and Lloyd Freese above the Tatshenshini River. 1992. Photo credit unknown.

At that time, he also became a Royal British Columbia Museum research associate and started working on a complete taxonomical and ecological treatment of approximately 360 taxa in the Asteraceae (sunflower family) in British Columbia. Unfortunately, only two of the planned three volumes were ever published due to funding difficulties. He was also involved in numerous articles and government documents in the 1980s, and he edited and contributed to an attractive and informative coffee table book on Kluane Park, Yukon, called *Kluane, Pinnacle of the Yukon* (Theberge and Douglas Editors 1980). His work in the Yukon also resulted in the *Rare Vascular Plants of the Yukon* (Douglas et al. 1981).

George also established a strong relationship with ecologists in the British Columbia Ministry of Forests (MOF) in the 1980s as well as the 1990s. He worked on floristic manuals and bibliographies for them, and annotated several thousand sheets of British Columbia plants. George and his colleagues at MOF (Del Meidinger, Andy Mackinnon and Jim Pojar) felt that it was of utmost importance to have a flora for British Columbia to provide a foundation for all inventory, floristic and conservation work going on within the province. Therefore, he collaborated with them on the very first flora for British Columbia and became the chief editor of the *The Vascular Plants of British Columbia* (Douglas et al. 1991-1994). For the first time ever, botanists had a flora for British Columbia all in one work. Previously, botanists had to carry a variable number of floras depending on what part of the province they were working in.

In the 1990s, George was also involved in the following very popular field guides: *Plants of Northern British Columbia* (MacKinnon et al. 1992), *Plants of the Southern Interior of British Columbia* (Parish et al. 1996), and the second, expanded edition of the *Mountain Plants of the Pacific Northwest* (Taylor and Douglas 1995). In total, he contributed approximately 45 publications during that decade that greatly enhanced the knowledge of vascular plants in British Columbia and the Pacific Northwest.

In addition to his valuable contributions to the botanical literature, George also added thousands of valuable collections to major herbaria in Canada. During his career, he collected 13893 specimens, many of which represented new taxa for the province, new range extensions for known taxa, rare or at-risk species, and other interesting finds. From his collections in the Cascade Mountains he and John Packer named a new *Erigeron* (fleabane) for the Pacific Northwest, *Erigeron salishii* (Salish Daisy) (Douglas and Packer 1988). He also made the first collections in British Columbia of species like *Orthocarpus barbatus* (Grand Coulee Owl-clover), *Erigeron leibergii* (Leiberg's Fleabane), and *Tonella tenella* (Small-flowered Tonella).

In 1991, George started working for the British Columbia government as the Program Botanist at the CDC. This position gave him the opportunity to further contribute to floristics in British Columbia through the CDC mission of identifying, tracking, and monitoring the rarest or most at-risk plants in the province. To accomplish this goal, George continued to collect and amass important collections. In addition, through inventory work, George travelled throughout the province chasing the plants that were on the CDC's tracking list and surveying a wide variety of habitats, including range lands, wetlands and mountain tops. The year that I joined the CDC, we toured the peaks of the southern Rocky Mountains for five days via helicopter escort. Because of his background in alpine ecology, mountain excursions were definitely a focus for George, but also critical was our inventory work in the other habitats for rare plants, such as the sand dunes of the west coast of Vancouver Island, the hot springs in the East Kootenays, and the beaches of Osoyoos Lake. These trips sound like a series of holidays but that was where our work took us to confirm the conservation status of rare and at-risk plants in British Columbia.

In order to accurately survey and track the species, George not only saw the need for meticulous inspection of the herbaria collections and for inventory work in poorly surveyed areas as well as in regions under high development pressure, but he also saw the need for an updated flora. Therefore, in the late 1990s he started focusing his efforts on the production of the *Illustrated Flora of British Columbia* (Douglas et al. 1998-2002). At that time, he also co-authored the *Rare Native Vascular Plants of British Columbia* (Douglas et al. 2002) so that land use planners and field workers had an easy-to-use reference to the CDC-listed plants.

The *Illustrated Flora of British Columbia* (Douglas et al. 1998-2002) dominated George's life from the late 1990s to 2002. Since he was so dedicated to its completion, he worked on it at home as much as he did in the office. The production of the flora not only involved coordinating the contributors' schedules, keeping them on timelines and reviewing the products, but it also involved compiling high quality illustrations (some borrowed, others newly commissioned). The maps were a whole other project (published in Volume 8 of the series) – the first complete set of distribution maps for British Columbia plants ever done. It was an enormous effort but with enormous benefits.

The inventory work that George was involved with at the CDC not only allowed for more accurate provincial listing of rare and at-risk taxa, but also allowed him to prepare numerous status reports on the local southeast Vancouver Island and Okanagan Valley Endangered and Threatened plant taxa. As a result of these studies, he authored and co-authored 40 Committee on the Status of Endangered Wildlife in Canada (COSEWIC) status reports and update status reports, more than any other contributor of reports to the national species assessment team!

Along the way, George encouraged many of the individuals that he mentored to co-author status reports. He often invited enthusiastic students and other protégés to join him on field outings where he was very forthcoming about sharing his botanical knowledge. He also spent time helping the Co-operative Education students that worked at the Royal British Columbia Museum and many others that sought his advice. He encouraged his staff with regular bouts of appreciation. Every year, at Christmas his botanical supporters at the CDC were invited to lunch at his favourite spot, The Royal Colwood golf course clubhouse, where patrons have a great view of the lovely grounds with its ancient Douglas-firs and Garry Oaks, manicured greens and ponds.

Through his work it was obvious that George was a conservationist at heart. He may not have portrayed the image of one in the typical sense, but he always extolled the virtues of preserving natural areas. In the early 1990s, he participated in the Sierra Club expedition down the Tatshenshini River, northern British Columbia, part of a successful campaign to have a protected area established in there (Figure 2).

He became a member of the Garry Oak Ecosystem Recovery Team Rare Plant Recovery Implementation Group, and contributed valuable input to the membership discussions. He was also on the *Adiantum capillus-veneris* (Maidenhair Fern) recovery team and performed an advisory role to the South Okanagan-Similkameen Conservation Program. In his consulting work, he contributed to conservation through research and inventory, but also through work with golf clubs advising them on how to create environmentally friendly courses.

He also supported an important Nature Conservancy of Canada campaign to purchase one of the last remaining sizeable stands of Garry Oak in semi-pristine condition left on southeastern Vancouver Island, a property owned by the Elkington family, located east of Duncan. He did early inventories in the Garry Oak ecosystem, and advised the Nature Conservancy staff about the biodiversity values of the property during the raising of funds to purchase it. In 1999, George had the opportunity to conduct the most intensive and objective study of a Garry Oak woodland ever done in British Columbia on this very property, later coined the "Cowichan Garry Oak Preserve". The study examined the composition, phenology, stand structure, and soils of the Garry Oak woodland. Phenological data was obtained on a weekly basis from March until September and soils were also examined in detail from three soil pits. In 2004, Douglas Ecological Consultants Ltd. repeated the vegetation component of the study to monitor changes after five years (Smith and Douglas 2005).

During his government career, George reached out to many different groups to communicate his message to protect rare and at-risk plants. In particular, he established a relationship with Osoyoos Indian Band, and befriended Environmental Officer Ron Hall. He spent

many summers doing inventories on Osoyoos band lands monitoring the special habitats that they have conserved over the years in the region, while all surrounding properties have been converted to vineyards, orchards, golf courses, and residential and commercial developments. Even after he retired from government in 2002, he continued to work with the band helping them with invasive species control in sensitive rare plant habitats.

When George retired from government after 11 years of service in early 2002, he started up Douglas Ecological Consultants Ltd. full-time once again. He was very excited about getting out in a consulting capacity like the "old days" on some field trips since the inventory work had been scant in recent years with the government. In his capacity as a consultant to government, he became active in a variety of interesting botanical and ecological projects and produced many reports. In the last three years of his life, he worked on numerous status reports, four species at risk recovery strategies, and one multi-species recovery strategy. Sadly, his life and work were cut short by a long battle with cancer. He died on 10 February, 2005 at Cowichan District Hospital, Duncan, British Columbia. He left behind wife Sylvia, son Geordie, daughter-in-law Mary McPhail, and grandchildren Mackenzie and Ryder, his four siblings and numerous nieces and nephews.

He has, however, left a truly inspiring legacy. His botanical contributions are used often by many plant lovers, botanists and ecologists in British Columbia and beyond. He will be remembered as a leader, not a follower, who made things happen. He was hard-working and passionate about his work. His lengthy bibliography and professional experience, which follows, will attest to this assertion.

Other tributes to George W. Douglas appeared in *Botanical Electronic News (BEN)*, the first, an obituary written by his MOF colleagues, Del Meidinger, Jim Pojar and Andy MacKinnon, and the second, a tribute to George's immense bibliography (http://www.ou.edu/cas/botany-micro/ben/ben344.html; http://www.ou.edu/cas/botany-micro/ben/ben351.html). The bibliography found in this article is an updated version of the one that was published in October of 2005 in "*BEN # 351*" and is found at http://www.ou.edu/cas/botany-micro/ben/suppl/351/gwdouglas.html.

An obituary also appeared in the local Duncan and Victoria papers that featured one of George's favourite pictures with his beloved cat, Garfield, where the two of them are reading a Czech satirical, antimilitaristic novel from the First World War given to him many years ago by a valued colleague (Figure 3; http://www.obituariestoday.com/Obituaries/ObitSearchList.cfm).

FIGURE 3. George and his beloved cat, Garfield. Circa 1993. Photo by Sylvia Douglas.

Acknowledgments

Thanks to Sylvia Douglas for important insights into an era in George's life that pre-dates me and for editing help. Thanks also to Brenda Costanzo, Adolf Ceska, Sharon Hartwell, Diana Demarchi, Frank Lomer, Marie Malo (née Fontaine), Gail Harcombe, Marta Donovan, and Del Meidinger who graciously provided review comments. George would have appreciated that they contributed to the article.

Positions in Scientific and Professional Societies

Member: Northwest Scientific Association; Ottawa Field-Naturalists' Club; Rare Plant Consortium; Association of Professional Biologists

Research Associate: Royal British Columbia Museum (1991-2004).

Dissertations and Post-doctoral Fellowships

Douglas, G. W. 1970. A vegetation study in the subalpine zone of the western North Cascades, Washington. M.Sc. thesis, University of Washington, Seattle, Washington. 293 pages.

Professional Experience Summary

1966 – 1967: Forester and Consultant with Rayonier, Canada Ltd., Jeune Landing, BC and Mills, and Potter and Mills, Vancouver, British Columbia, where he supervised forest inventory, forest type mapping, and reforestation projects on northern Vancouver Island, British Columbia.

1968 – 1970: Ecological Consultant to the Intercampus Education and Scientific Preserves Committee (Washington Universities) at Western Washington State College, Bellingham, Washington, hired to examine and quantitatively sample more than twenty-five potential natural areas throughout the State of Washington, and recommend which ones should be protected.

1969 – 1974: Ecological Consultant to the United States National Park Service in Sedro Woolley, Washington, where he initially provided a biological inventory (vegetation, wildlife, soils and geology) of the newly formed North Cascades National Park, Washington. He also conducted vegetation analysis of the entire park (18000 km^2) and provided advice and research with respect to vegetation problems.

1973 – 1974: Ecological Consultant to Canadian Wildlife Service, Edmonton, Alberta, and Parks Canada, Winnipeg, Manitoba. Project co-ordinator and chief ecologist examining vegetation and soils of Kluane National Park, Yukon Territory, and their relation to fragility and land use within the park. This study was also co-ordinated with small mammal and bird studies.

1973 – 1974: Ecological Consultant to Canadian Forestry Service, Edmonton, Alberta, reviewing and evaluating the ecological impact and use of chemical fire retardants in North America. He also made recommendations pertaining to the future use of chemical fire retardants in Canada.

1974 – 1975: Ecological Consultant to Canadian Wildlife Service, Edmonton, Alberta, and Parks Canada, Calgary, Alberta. Project co-ordinator and chief plant ecologist for a study designed to assess the environmental impact of recreational use (mainly human and horse trampling) on different vegetation types in Waterton Lakes National Park, Alberta.

1974 – 1975: Ecological Secretariat, Department of Lands and Forests, Victoria, British Columbia. Chief plant ecologist on a three-faceted study in west-central British Columbia. The study included a vegetation reconnaissance of a 1500 square mile area, examination of the spruce hybridization problem in the region, and an evaluation of the ecological reserve system and selection in British Columbia.

1974 – 1975: Ecological Consultant with Don Blood & Associates Ltd., Lantzville, British Columbia, for Parks Canada, Winnipeg, Manitoba. Chief plant ecologist with a biological and geological team assessing the environmental impact of five potential transportation corridors in Kluane National Park, Yukon Territory.

1975 – 1977: Ecological Consultant to Syncrude Canada Ltd., Edmonton, Alberta. This project involved setting up a continuous biological monitoring program for air quality in the tar sands refinery area near Fort McMurray, Alberta. Using lichens as an indicator, the affect of effluents (especially SO_2) and their environmental impacts will be continuously evaluated.

1975 – 2004: Research Associate in Biological Collections, Herbarium, Royal British Columbia Museum, Victoria, British Columbia. Author of a flora on the Asteraceae (Sunflower family) of British Columbia. This work includes a complete taxonomical and ecological treatment of approximately 350 taxa.

1975 – 1979: Ecological Consultant to Parks Canada, Winnipeg, Manitoba. Project co-ordinator and chief plant ecologist on four-year Biophysical Inventory Project in Kluane National Park, Yukon Territory. This multidisciplinary study included landforms, surficial deposits, vegetation, and soils. A total of ten professional scientists were involved in this study.

1977 – 1978: Ecological Consultant to Thurber Consultants Ltd., Victoria, British Columbia, with Department of Public Works Canada, Vancouver, British Columbia. Chief plant ecologist on environmental impact study team. This multidisciplinary study included all aspects from engineering and social to environmental impacts with respect to the paving and relocation of a large section of the Alaska Highway.

---

* In the production note, COSEWIC acknowledges the late George W. Douglas and Ms. Shyanne J. Smith for writing the status report.

** In the production note, COSEWIC acknowledges the late George W. Douglas and Jacques Labreque for writing the status report.

1978 – 1979: Ecological Consultant to Department of Public Works, Canada – Whitehorse, Yukon Territory. Chief plant ecologist on environmental impact study. Assessed the environmental impact of Alaska Highway relocation and paving between Watson Lake and Haines Junction.

1978 – 1980: Ecological Consultant with Hardy and Associates Ltd. for Department of Public Works, Canada in Whitehorse, Yukon Territory. Chief plant ecologist on revegetation project. This multidisciplinary study examined vegetation and soils and recommended reclamation procedures for a 175 mile segment of the Alaska Highway.

1979 – 1980: Ecological Consultant to British Columbia Ministry of Environment, Land and Parks, Victoria, British Columbia. Designed and coordinated a biological monitoring network (using lichens) in northeastern British Columbia.

1980: Ecological Consultant to Ecological Reserves Unit, British Columbia Ministry of Environment, Victoria, British Columbia. Provided an assessment of alpine plant communities in British Columbia and adjacent regions and their occurrence in existing or proposed ecological reserves.

1981 – 1986: Taxonomical Consultant to British Columbia Ministry of Forests, Victoria, British Columbia. Provided editorial assistance for floristic manuals and prepared several reports, including a floristic bibliography. Identified and annotated several thousand sheets of British Columbia plant material.

1985: Taxonomical Consultant to National Museums of Canada, Ottawa, and World Wildlife Fund. Prepared detailed status reports on four Endangered vascular plants of British Columbia.

1985 – 1986: Interpretive Consultant to British Columbia Provincial Parks, Liard Hotsprings, and Mt. Robson Provincial Parks. Provided interpretive services for Provincial Parks summer interpretive programs.

1986 – 1995: Taxonomical Consultant to British Columbia Ministry of Forests, Victoria, British Columbia. Chief editor and major contributor for the four-volume *Vascular Plants of British Columbia*.

1987: Ecological and Taxonomical Consultant for British Columbia Provincial Parks, Strathcona Provincial Park, with Donald A. Blood & Associates, Nanaimo, British Columbia. Provided ecological and floristic expertise with respect to a preliminary assessment of natural resources.

1988 – 1989: Ecological and Taxonomical Consultant to British Columbia Ministry of Parks, Ecological Reserves Unit, Victoria, British Columbia. Chief co-ordinator for study team (including Blood & Associates and Westland Resources Group) formulating a new ecological reserve system for British Columbia.

1991 – 2002: Program botanist at British Columbia Conservation Data Centre, British Columbia Ministry of Environment, Lands and Parks, Victoria, British Columbia. Responsible for the tracking and inventorying vascular plants of conservation concern in British Columbia.

1992: Botanist, Sierra Club expedition down the Tatshenshini River, northern British Columbia; part of the campaign to have a protected area established in the region.

2001 – 2004: Recovery team member and scientific advisor, Garry Oak Ecosystem Recovery Team Plants at Risk Recovery Implementation Group.

2002: Recovery team member and scientific advisor, *Adiantum capillus-veneris* Recovery Team.

2002: Ecological Consultant to Parks Canada, Pacific Rim National Park. Chief botanist involved in inventory and invasive species management.

2003: Botanical consultant to British Columbia Ministry of Environment. Chief botanist on inventory projects in South Okanagan Grasslands Protected Area and adjacent parcels.

2003: Botanical Consultant to British Columbia Ministry of Environment. Chief Botanist hired to inventory for *Silene spaldingii* to fill information gaps in its current status in the province.

2003: Botanical Consultant to Parks Canada. One of chief botanists hired to inventory rare plants on the Queen Charlotte Islands.

2003 – 2004: Botanical Consultant to Osoyoos Indian Band. Botanist and Project Coordinator managing invasive species in sensitive habitats on band lands. Also trained band members in managing the vegetation.

2004: Botanical Consultant to British Columbia Ministry of Environment. Chief botanist hired to inventory *Azolla mexicana* to fill information gaps in its current status in the province.

1974 – 2004: Principal of Douglas Ecological Consultants Ltd. Botanist, Ecologist and Project Director.

Conservation Evaluation of the Prairie Lupine, *Lupinus lepidus* var. *lepidus*, in Canada*

GEORGE W. DOUGLAS[1] and MICHAEL RYAN[2]

[1] Deceased
[2] Present address: 801 Frayne Road, RR # 1, Mill Bay, British Columbia V0R 1L0 Canada

Douglas, George W., and Michael Ryan. 2006. Conservation evaluation of the Prairie Lupine, *Lupinus lepidus* var. *lepidus*, in Canada. Canadian Field-Naturalist 120(2): 147–152.

In Canada, Prairie Lupine, *Lupinus lepidus* var. *lepidus*, is restricted to southeastern Vancouver Island. Of the nine sites where it has been collected, five are extirpated and the status of two of the populations is uncertain. There are two extant populations; some of the other sites may contain the species in the seed bank. Some of the sites are protected to a certain extent from direct habitat destruction by their remote location, although introduced herbaceous species may pose a serious threat by preventing the establishment of the species at other sites. Fire suppression or the lack of other types of disturbance also likely plays a role in discouraging emergence of *Lupinus lepidus*.

Key Words: Prairie Lupine, *Lupinus lepidus*, endangered, distribution, population size, British Columbia.

The Prairie Lupine, *Lupinus lepidus* Dougl. ex Lindl. var. *lepidus*† is a member of a genus of over 100 species. Most of these occur in North America but the genus occurs on all continents except Australia (Hitchcock et al. 1961). It is one of 20 species of *Lupinus* occurring in British Columbia (Pojar 1999) and of about 27 species in Canada (Scoggan 1978). The genus is of some economic importance in the horticultural trade.

The *Lupinus lepidus* complex has been a source of difficulty to researchers over the years. Hitchcock et al. (1961) state that although the *L. lepidus* complex is distinct, the variation within this group has resulted in a large number of proposed subspecies and varieties of which some are considered to be distinct species by others. According to Phillips (1955), the nomenclature is even more confusing, and the number of synonyms is greater for *L. lepidus* than for any other *Lupinus* species. The work of Detling (1951), Phillips (1955) and Dunn and Gillett (1966) has improved the nomenclature and delineation of *Lupinus* species but many problems remain.

The type specimen of *L. lepidus* var. *lepidus* was collected by David Douglas from "... Fort Vancouver to the Great Falls of the Columbia". Subsequently, Hitchcock et al. (1961) recognized five varieties of *L. lepidus* two of which, var. *lepidus* and var. *lobbii* (A. Gray) C. L. Hitchc., are reported to occur in British Columbia. The latter variety is considered to be a separate species (*L. lyallii* A. Gray) in more recent floras of Canada and British Columbia (eg., Dunn and Gillett 1966; Taylor 1974; Scoggan 1978; Douglas 1990; Pojar 1999) and occurs on well-drained soils in subalpine and alpine areas (Douglas 1990; Douglas and Bliss 1977).

Lupinus lepidus var. *lepidus* as recognized by Hitchcock et al. (1961), Douglas (1990), Douglas et al. (1998a) and Pojar (1999), included *L. minimus* Dougl. in synonomy but they failed to account for the location of the type specimen (Rocky Mountains, Kettle Falls in the upper Columbia River drainage) or the range of *L. minimus* in the western Cordillera east of the Coast-Cascade Mountains. *Lupinus minimus* is considered by other authors to be a separate species (e.g., Cox 1973a, 1973b; Dunn and Gillett 1966; Scoggan 1978; Taylor 1974). Douglas et al. (2002a, 2002b) also now treat *L. minimus* as a distinct entity. The latter has been reported to occur in the Columbia River drainage of southern British Columbia (Dunn and Gillett 1966; Taylor 1974), but no specimens have been located. It is also reported to occur in the Crowsnest area of Alberta (Dunn and Gillett 1966) and, more recently, in and adjacent to Waterton Lakes National Park (Argus and White 1978; Kuijt 1982) and at six locations near the southern Alberta border (Packer 1983). Both Kuijt (1982) and Packer (1983) consider *L. minimus* to be synonymous with *L. lepidus*.

Lupinus lepidus is a multi-stemmed perennial herb 20-45 cm tall (Figure 1; Pojar 1999). The stems are slender with long, soft hairs. The plant has oblanceolate palmate compound leaves that are 5 to 9 foliate and copiously silky-hairy. The leaves are mostly basal with only 1 to 4 leaves on the stem. The petioles are 2-5 times as long as the blade. The racemose, pea-like

*The original field work for the *Lupinus lepidus* project was funded by the British Columbia Conservation Data Centre. The results appear in the British Columbia Conservation Data Centre database and a rare plant manual (Douglas et al. 2002a). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Ryan and Douglas 1996*) and the subsequent assessment of *endangered* (COSEWIC 2000*). This paper includes more recent information that did not appear in the original status report.

†Taxonomy and nomenclature follow Douglas et al. (1998b, 1999, 2001a, b) and Pojar (1999).

blue flowers are similar to those of other Fabaceae species. The petals are 8-13 mm long, and the banner is often lighter or darker and reflexed below the midpoint. The wings are glabrous, the keel ciliate, and the calyx silky-hairy. Both lips are 6-7 mm long, the upper ones of which are bifid for at least half their length. Peduncles are 9-10 cm long, pedicels are 2 mm long and petals are 8-13 mm long. The hairy pods are 1-2 cm long and contain three to five large seeds. In British Columbia, it is separated from three similar looking species by its distinct range in the coastal lowlands on southeastern Vancouver Island. It is distinguished from most other species of *Lupinus* by its small stature, the white appressed hairs covering the stems and leaves and the thick caudex at the base of the plant.

Distribution

Lupinus lepidus extends from southwestern British Columbia to north-western Oregon, west of the Cascade Mountains (Douglas et al. 1990; Pojar 1999). In Canada it is rare on southeastern Vancouver Island, British Columbia (Figure 2; Douglas et al. 2002a; Pojar 1999).

Habitat

Lupinus lepidus inhabits xeric sites ranging from grass-dominated meadows to steep rocky slopes where the vegetation is comprised of scattered clumps of Douglas-fir (*Pseudotsuga menziesii*), Arbutus (*Arbutus menziesii*), and Lodgepole Pine (*Pinus contorta* var. *contorta*). These sites are restricted to southeastern Vancouver Island, where rainfall is low compared to other coastal areas in British Columbia, and during the summer, they often experience an extended period of drought. Associated species include Scotch Broom (*Cytisus scoparius*), Hedgehog Dogtail (*Cynosurus echinatus*), Sweet Vernalgrass (*Anthoxanthum odoratum*), several species of Brome (*Bromus*), and Common Camas (*Camassia quamash*). The habitat at the Somenos site was unnatural, consisting of gravel deposited during railroad or highway construction.

TABLE 1. Populations of *Lupinus lepidus* in Canada.

Collection Site	Last Observation	Collector/ Observer	Population data (plants/area in m^2)
Langford Plains (Victoria)	1908	Macoun	Extirpated
Observatory Hill (Victoria)	1915	Newcombe	Extirpated
Koksilah River Valley (Duncan)	1960	Hardy	Unknown
Cattle Point (Victoria)	1973	Brayshaw	Extirpated
Beacon Hill (Victoria)	1993	Brayshaw	Extirpated
Somenos Lake (Duncan)	1994	Douglas	Extirpated
Mount Wells (Victoria) (2 plants/1 m^2 in 2003)	2006	Roemer	No plants
Mount Braden (Victoria)	2005	Roemer	2 plants
Mount McDonald (Victoria)	2005	Roemer	113 plants/75 m^2

Biology

Little is known regarding the biology of *Lupinus lepidus*. However, many species of *Lupinus* share common traits, some of which likely characterize *L. lepidus*. It is likely to be associated with nitrogen-fixing *Rhizobium*, which may allow it to invade sites where soils are low in nitrogen. It is suspected that *L. lepidus* is a short-lived colonizer of recently disturbed sites in xeric, open, exposed areas where it persists for several years. It eventually declines, possibly from competition with more aggressive species that either directly compete for resources or prevent the establishment of seedlings, or from lack of vigour in mature plants. The seeds may not have any dormancy requirements but like other legumes, *L. lepidus* seeds have a hard seed coat which may delay germination for several months or years. Nothing is known regarding pollination, seed set, and survival rates.

Population Attributes

Of the nine Canadian sites from which *Lupinus lepidus* has been collected (Table 1, Figure 2), five populations are extirpated. Another two sites (Koksilah River and Mount Wells) are assumed extant but their status is unknown. Little is known regarding population trends for this species. Monitoring this taxon is difficult because populations may only be comprised of a few plants and therefore, easily overlooked, or they may remain in a seed bank for an unknown period before reappearing. However, four years of data collected at Somenos Lake (extirpated) showed a decline before it was destroyed at the site: 250, 1, 0, and 1 in 1991, 1992, 1993 and 1994, respectively. Other sites with limited data include Mount Wells, which contained nine plants in 2001, only a few plants in 2002, two plants in 2003, and no plants in 2004, 2005 and 2006 (H. Roemer, personal communication). The steady decline at this site is attributed to the re-growth of shrubs following a fire. In addition, in 2005, two plants were observed on Mount Braden (up from single plant in 1996) and 113 plants were observed on Mount McDonald (where they had only previous been known from 1915). In 2006, a single plant was seen on Mount Braden and 54 plants on Mount McDonald, but a thorough search of all the locations from 2005 was not done and therefore, the population should not be considered in decline.

Provincial, National, and Global Ranks

The British Columbia Conservation Data Centre has ranked *Lupinus lepidus* as S1 and placed it on the British Columbia Ministry of Environment Red-list (Douglas et al. 2002a). This is the most critical category for imperiled rare native vascular plants in British Columbia. A rank of S1 is considered "critically imperiled because of extreme rarity (5 or fewer occurrences or very few remaining individuals) or because of some factors making it especially vulnerable to extirpation or extinction" (Douglas et al. 2002a). *Lupinus lepidus* is on the Canadian *Species At Risk Act* legal list and the Committee on the Status of Endangered Wildlife in Canada has also assigned this species to the Endangered category (COSEWIC 2000*). Globally, it is ranked G5 or common and secure in its range (NatureServe 2006*).

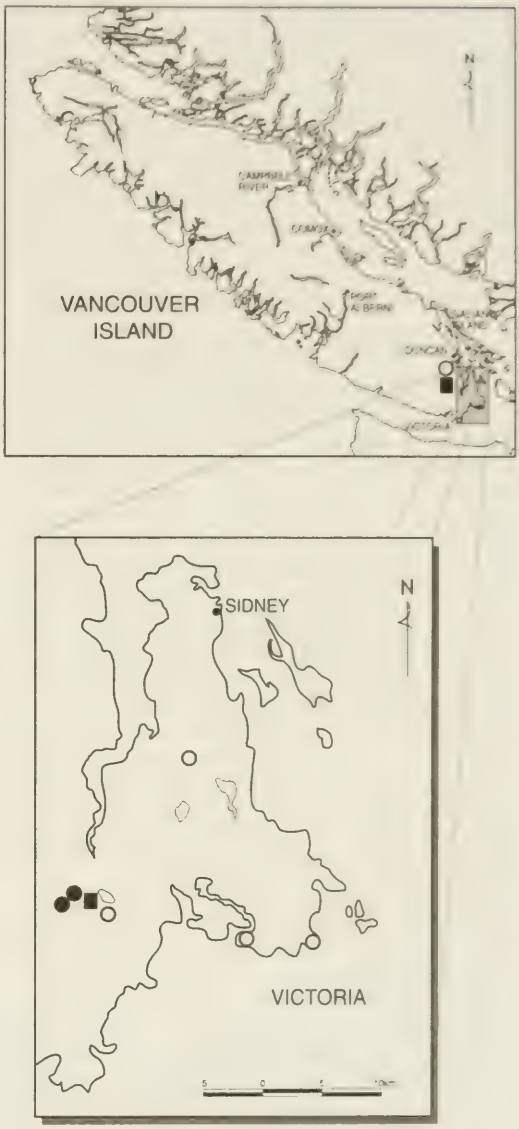

FIGURE 2. The status and location of *Lupinus lepidus* in British Columbia. ● recently confirmed; ■ present status unknown; ○ extirpated

Threats and Protection

The most direct threat to *Lupinus lepidus* is habitat destruction. Grass-dominated meadows, often associ-

ated with Garry Oak-Brome (*Quercus garryana-Bromus*) stands, commonly occurred on gentle slopes on the most climatically favourable coastal areas on south-eastern Vancouver Island and some of the Gulf Islands prior to European colonization. Since colonization both types of vegetation have been subjected to extensive agricultural and residential development. Their destruction has continued to the present, resulting in the elimination of almost all sites occurring outside parks or ecological reserves. The loss of these habitats, estimated at 95% (Lea 2002), severely reduces the availability of sites for the establishment of *L. lepidus* var. *lepidus* and imposes severe limitations on the long-term survival of this species in Canada.

Introduced species including *Cytisus scoparius*, *Cynosurus echinatus* and *Anthoxanthum odoratum* now dominate *L. lepidus* habitats, further threatening the survival of this species. The introduction of aggressive European species has resulted in substantial changes to the grass-dominated meadows associated with *Quercus garryana*, and rocky xeric sites in the Victoria area. *Cytisus scoparius,* in particular, has been one of the most devastating species. It has become a dominant shrub on xeric, exposed sites throughout much of south-eastern Vancouver Island and the Gulf Islands.

Furthermore, the suppression of natural and unnatural periodic fires appears to have resulted in changes to the vegetation of many sites where this species would be expected to occur. In the past, aboriginal peoples may have set fire to these sites to maintain them as an important habitat for wildlife (Roemer 1972). This would have destroyed much of the competing vegetation and created habitats where *L. lepidus* would have had the opportunity to become established. However, since that time, these sites have experienced little disturbance, resulting in invasion and expansion by trees, shrubs, and especially introductions, which effectively eliminate many herbaceous species.

In Canada, some populations of *L. lepidus* are protected to a certain extent by their location on public property. This was not the case, however, for the plant in Beacon Hill Park which was destroyed by maintenance activites along a roadbank in 1994, or for the population on the highway right-of-way at Duncan, which was also destroyed and covered in 1994 by heavy equipment used in a North Cowichan Municipality sewer line project. Extirpation is also a probable fate at Cattle Point and Observatory Hill. Even though Cattle Point is located in a municipal park, it is not protected from trampling by pedestrians and mountain bike enthusiasts. During the summer months, tour buses arrive at this park many times each day resulting in large numbers of people trampling the vegetation along the shoreline and adjacent rock outcrops. As a result of these activities, much of the vegetation has been degraded to the point where the number of potentially suitable habitats for the establishment of *L. lepidus* are far fewer today than in the past. The population could also have been overcome if it occurred in areas now dominated by shrubs.

Observatory Hill is owned by the federal government and is home to the Dominion Astrophysical Observatory. Much of the vegetation has been replaced by exotic species but access is limited to a single road. Although further development on the hill is unlikely to occur, many of the suitable habitats in which *L. lepidus* would likely be found are infested with *Cytisus scoparius*.

Populations at Mount McDonald and Mount Braden are protected by their location within either the Greater Victoria Watershed District (which supplies drinking water to Victoria and adjacent communities and prohibits public access) or the CRD Sooke Hills Wilderness, respectively. Since these areas are dominated by steep rocky terrain and since there are few trails, vegetation has not been degraded to the same extent as it has in more accessible areas near Victoria.

The specific site at which *L. lepidus* was collected in the Koksilah River Valley is not known, thus it is not possible to provide any information on the extent to which this population is protected. However, if it is located on a steep, rocky, xeric sites similar to those found on Mount McDonald, Mount Braden, and Mount Wall, it is unlikely to be threatened in the near future by development or habitat destruction.

The site on Mount Wells is on private land but is not easily accessed at the present time. Nearby mountains, however, have been subject to housing developments in recent years thus the site of *L. lepidus* is not necessarily secure.

Lupinus lepidus is not formally protected in British Columbia, however, it could be in the future since this species is a potential candidate for listing under the provincial *Wildlife Amendment Act* (2004). As part of its commitment to the National Accord (*National Accord for the Protection of Species at Risk*), the province is required to take measures to protect this species. It is on Schedule 1 of the federal *Species At Risk Act* and a recovery strategy (which treats *Lupinus lepidus* in addition to several other species-at-risk) has been proposed (Parks Canada Agency 2005*). The recovery strategy is a planning document that identifies what needs to be done to arrest or reverse the decline of a species. Detailed planning is done at the action plan stage. However, an action plan is not currently available, nor are there any stewardship activities that are currently being implemented.

Evaluation

The Committee on the Status of Endangered Wildlife in Canada and the British Columbia Conservation Data Centre consider *Lupinus lepidus* to be endangered in Canada (Douglas et al. 2002a). It has only been collected nine sites in Canada, only three of which have recently been confirmed, all confined to southeastern Vancouver Island. It is believed to be extirpated at five

of these sites and has not been confirmed recently at two sites. The prognosis for this species is not good considering the threats posed by aggressive competitive species. The loss of suitable habitats at other sites to residential development severely limits the potential of this species to become established at new sites. Furthermore, fire, which may have been an important agent in the continued existence of this species in British Columbia, is now actively suppressed. With so little information known on the ecology of *L. lepidus*, and on its relationship to the environment and other species, successful management of the species is hampered.

Acknowledgments

Special thanks to Hans Roemer, whose persistent searches during recent years continue to reveal *Lupinus lepidus* sites. Thanks also to Jenifer Penny for office assistance.

Conservation Evaluation of the Seaside Birds-foot Trefoil, *Lotus formosissimus*, in Canada*

GEORGE W. DOUGLAS[1] and MICHAEL RYAN[2]

[1]Deceased.
[2]Present address: 801 Frayne Road, RR #1, Mill Bay, British Columbia V0R 1L0 Canada.

Douglas, George W., and Michael Ryan. 2006. Status of the Seaside Birds-foot Trefoil, *Lotus formosissimus*, in Canada. Canadian Field-Naturalist 120(2): 153-156.

In Canada, Seaside Birds-foot Trefoil, *Lotus formosissimus*, is restricted to the Victoria area on southeastern Vancouver Island and two adjacent islands. Populations at five sites are extant and have been recently inventoried, whereas populations at two or more sites in Victoria are extirpated. Existing populations represent the northern range limits of *L. formosissimus*. Although known populations are protected to a certain extent from direct habitat destruction, introduced herbaceous species may pose a serious threat to the continued existence of most populations and may prevent the establishment of *L. formosissimus* at other sites. Fire suppression, grazing, encroachment and low survivorship are also limiting factors.

Key Words: Seaside Birds-foot Trefoil, *Lotus formosissimus*, endangered, distribution, population size, British Columbia.

Seaside Birds-foot Trefoil, *Lotus formosissimus* Greene, is a member of a genus of about 200 species occurring throughout the world, primarily in temperate zones. It is one of nine species occurring in British Columbia and Canada, four of which have been introduced from the Old World (Pojar 1999; Scoggan 1978).

Lotus formosissimus is a sprawling or ascending, multi-stemmed perennial that grows from a short rootstock and thick taproot to 20-50 cm tall (Figure 1; Pojar 1999). It has compound, pinnate leaves 4-8 cm long with 3 to 7, ovate to obovate leaflets. The three to five yellow and pink pealike flowers are 10-15 mm long and arranged in umbels. The umbels are borne on axillary peduncles 2-6.5 cm long and are usually subtended by trifoliate bracts. The wings of the flowers are pinkish to purplish tinged, the keel is purple tipped, and the banner is yellow and 11-15 mm long. The wings and clawed keel exceed the calyx considerably. Pods are 27-36 mm long by 1.5-2 mm wide and enclose 7 to 15, dark brown to black seeds. *Lotus formosissimus* is distinguished from other *Lotus* species by its perennial habit, membranous stipules, trifoliate bracts (sometimes unifoliate), and pink and yellow flowers (Ryan and Douglas 1994*, 1996*). Bog Bird's-foot Trefoil (*L. pinnatus*) also has yellow but never pink corollas.

FIGURE 1. Illustration of *Lotus formosissimus*. (Line drawing from Pojar 1999).

Distribution

Lotus formosissimus is restricted to the west coast of North America, from southeastern Vancouver Island to central California (Isely 1993; Pojar 1999). In Canada, it is restricted to southeastern Vancouver Island and nearby islands (Figure 2; Dunn and Gillet 1966; Pojar 1999; Douglas et al. 2002a, 2002b).

*The original field work for *Lotus formosissimus* was funded by the British Columbia Conservation Data Centre. The results appear in the British Columbia Conservation Data Centre database and a rare plant manual (Douglas et al. 2002a). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Douglas and Ryan 1996*) and the subsequent assessment of *Endangered*. This paper includes more recent information that did not appear in the original status report.

TABLE 1. Populations of *Lotus formosissimus* in Canada (in Victoria and west of Victoria at Department of National Defense – Rocky Point).

Collection Site	Last Observation	Collector	Population Status (number/area)
Oak Bay, Victoria	1896	Anderson	Extirpated
Foul Bay, Victoria	1912	Henry	Extirpated
William Head, W of Victoria	2002	Fairbarns	19/8 m^2
Bentinck Island, Rocky Point	2004	Fairbarns	278/110 m^2
Rocky Point, E side	2005	Fairbarns	36-53/75.5 m^2
Rocky Point, Church Point	2004	Fairbarns	209-327/137 m^2
Trial Island, Victoria	2004	Fairbarns	383/5000 m^2

Habitat

Lotus formosissimus grows in various coastal meadow and woodland habitats, ranging from open exposed grass-dominated meadows to exposed steep rocky sites inhabited by Garry Oak (*Quercus garryana*), to shaded Garry Oak-Brome (*Quercus garryana-Bromus*) forests. Associated species, which typically occur in the understory of *Quercus garryana* stands, include Lance-leaved Stonecrop (*Sedum spathifolium*), Sea Blush (*Plectritis congesta*), Nodding Onion (*Allium cernuum*), Menzies Larkspur (*Delphinium menziesii*), Orchard Grass (*Dactylis glomerata*), Sweet Vernalgrass (*Anthoxanthum odoratum*), Hairy Cat's-ear (*Hypochaeris radicata*), Common Velvet-grass (*Holcus lanatus*), Early Hairgrass (*Aira praecox*), Ribwort Plantain (*Plantago lanceolata*), and several species of brome (*Bromus*). *Lotus formosissimus* also occurs in vernal seeps. It is suspected that *L. formosissimus* is a poor competitor with a number of perennial grasses because it is absent in a number of grass-dominated micro-sites that are otherwise apparently suitable habitats.

Biology

Little is known regarding the biology of *Lotus formosissimus*. It appears that *L. formosissimus* shoots emerge in spring followed by flowering between May and the end of June when moist soil conditions and warm temperatures are prevalent in *Quercus garryana* stands and meadows. By July, when drought conditions are prevalent, seed maturation and dispersal begin, followed soon thereafter by die-back of the stems to the rootstock, which is located several centimetres below the soil surface. In his demographic studies of *Lotus formosissimus*, M. Fairbarns (personal communication) discovered, based on ex situ experiments, that seeds may remain in the seed bank for at least two years. He postulated that this was a likely explanation for his in situ observations of higher numbers of seedlings than numbers of seeds set in the previous year.

Flowers likely require cross-pollination to set viable seed although pollinators have not yet been identified (Zandstra and Grant 1968). Seeds are believed to be easy to germinate (Hitchcock et al. 1961) but like other members of Fabaceae, they may have a hard seed coat, delaying the germination of seeds for several months or years. Mature plants may be long-lived and recruitment from germinating seeds is likely a rare event.

It is believed that *L. formosissimus*, like other legumes, is associated with nitrogen-fixing *Rhizobium* that provides the plants with an independent source of nitrogen from that in the soil.

Population Attributes

Lotus formosissimus has been collected at seven sites in Canada on southern Vancouver Island or adjacent islands (Table 1, Figure 2). Populations at two of these sites are considered extirpated. Other older collections not listed in Table 1 may or may not represent different locations (e.g., Victoria, and Oak Bay, Victoria). The population on Trial Island has been known since the 1950s and surveyors reported 28 plants in 1994 and 380 plants in 2004. Likewise, the population at Rocky Point has also been observed for over 20 years and was represented by 165 plants in 1993 and 245-380 plants in 2005. The increase, however, is likely attributable to different observers and different sampling methods. It is very unlikely that the populations are actually increasing significantly. The remaining sites have not been monitored for any length of time and thus, no information is available on population trends.

Provincial, National and Global Ranks

The British Columbia Conservation Data Centre has ranked this species as S1 and placed it on the Ministry of Environment Red list. This is the most critical category for imperiled rare native vascular plants in the province. A rank of S1 is considered "critically imperiled because of extreme rarity (five or fewer occurrences or very few remaining individuals) or because of some factors making it especially vulnerable to extirpation or extinction". *Lotus formosissimus* is on the Canadian *Species At Risk Act* legal list (COSEWIC 2000*) and globally, it is G5 or common and secure in its range (NatureServe Explorer 2006*).

Threats and Protection

In the past, the most direct threat to *Lotus formosissimus* was that of habitat destruction. Grass-dominated meadows, often associated with *Quercus garryana-Bromus* stands, commonly occurred on gentle slopes on the southeastern side of Vancouver Island and some of the Gulf Islands prior to European colonization. Since colonization, both types of vegetation have been subjected to extensive agricultural and res-

idential development and have been essentially eliminated outside parks or ecological reserves. Direct habitat destruction, however, is no longer the most important threat. It is the loss of suitable sites outside the current occupied area of *L. formosissimus* that severely limits the potential for this species to spread into new areas and therefore, threatens its long-term survival in Canada.

Less direct factors which threaten known populations include the introduction of aggressive European species. These species have resulted in substantial changes to the grass-dominated meadows associated with *Quercus garryana* and the rocky xeric sites in the Victoria area. One of the most devastating species is Scotch Broom (*Cytisus scoparius*). This species has become a dominant shrub on xeric, exposed sites throughout much of southeastern Vancouver Island and the Gulf Islands and either competes with native plants such as *L. formosissimus* for resources or prevents the establishment of their seedlings.

Furthermore, the suppression of natural and unnatural periodic fires may have resulted in changes to the vegetation of many sites where this species would be expected to occur. In the past, aboriginal peoples probably set fire to many of these sites to maintain them as an important habitat for food plants and wildlife (Roemer 1972). During the past century these sites have experienced little disturbance resulting in increased domination of some sites by trees and shrubs, especially introductions, that effectively eliminate many herbaceous species.

Another limiting factor is grazing. M. Fairbarns (personal communication) observed that grazing prior to seed set had greatly limited seed production and caused reduced vigour among established plants on Bentinck Island.

Finally, demographic constraints also play a role in the viability of populations. Fairbarns (personal communication) found low rates of juvenile survivorship and low levels of seed production. He found that they were related primarily to summer drought and grazing.

All extant populations of *L. formosissimus* in British Columbia are protected from heavy recreational pressure and disturbance caused by the general public. Although these sites contain a large number of introduced species, the latter were not nearly as abundant at Rocky Point, Bentinck Island, and Trial Island as they are at other public sites. It is very likely that restricted public access and lack of disturbance are the primary reasons for the continued existence of *L. formosissimus* at these sites.

The populations at Rocky Point and Bentinck Island are owned by the Department of National Defense. The Department of National Defence is aware of the location of rare species at Rocky Point and there are no plans to develop those areas in which *L. formosissimus* occurs. Bentinck Island is used by DND to detonate unused ammunition, but such activities do not coincide with

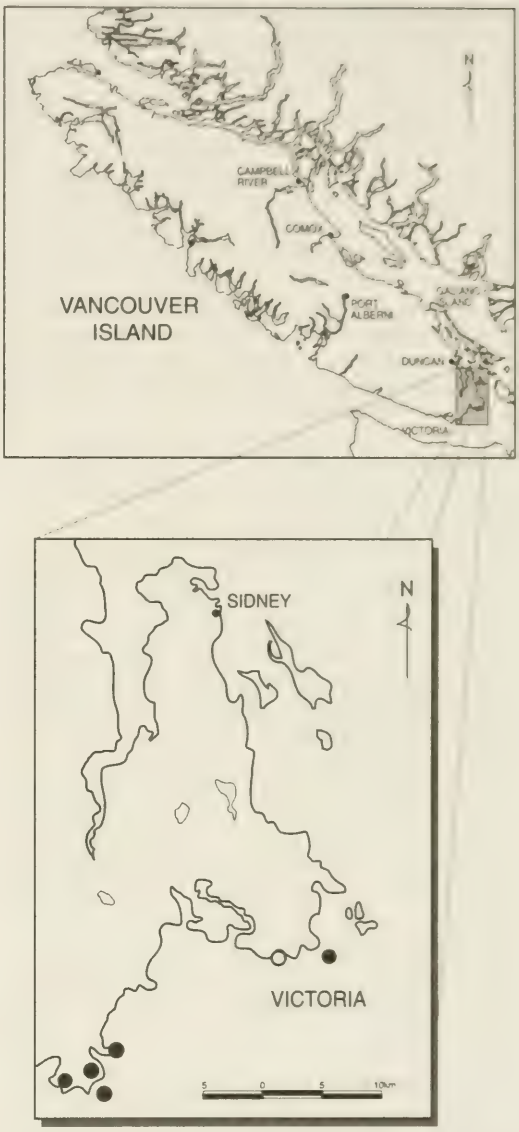

FIGURE 2. The status and location of *Lotus formosissimus* sites in British Columbia. ● – recently confirmed sites, ○ – extirpated site.

locations of *L. formosissimus* on the island. These populations are also protected by the Canadian *Species at Risk Act* by their occurrence on land under federal jurisdiction and therefore, are not likely to be directly harmed. The Canadian Forest Service is also involved in a number of projects with the goal of managing appropriately for species at risk on federal lands, including Scotch Broom removal from sites.

The *Lotus formosissimus* population in Trial Island Ecological Reserve is also provided with a high degree of protection. Despite its proximity to Victoria, it has

very limited public access because it is only accessible by boat, thus preventing excessive disturbance.

A recovery strategy (which treats *Lotus formosissimus* in addition to several other species-at-risk) has been proposed (Parks Canada Agency 2005*). The recovery strategy is a planning document that identifies what needs to be done to arrest or reverse the decline of a species. Detailed planning is done at the action plan stage. In the absence of an action plan, no attempts have been made to introduce *L. formosissimus* to suitable habitats or to increase the number of individuals at current locations. However, Scotch Broom removal at the Bentinck Island site has revealed additional *Lotus* plants (M. Fairbarns, personal communication). The site now offers improved conditions for growth and reproduction.

Evaluation of Status

The British Columbia Conservation Data Centre considers *Lotus formosissimus* to be endangered in Canada (Douglas et al. 2002a). The Committee on the Status of Endangered Wildlife in Canada has also assigned this species to the Endangered category (COSEWIC 2000*). Between 925 and 1060 plants are known from five sites on southeastern Vancouver Island and adjacent islands. The long-term survival of this species in Canada is dubious as a result of a number of limiting factors: shading by aggressive introduced species, poor survivorship, grazing, fire suppression and encroachment. Even though known populations are protected from excessive disturbance on federal lands and in the ecological reserve, the loss of suitable habitats at other sites severely limits the potential of this species to become established at new sites.

Acknowledgments

We thank Matt Fairbarns for population updates for all extant locations and Jenifer L. Penny for assistance in the office.

Conservation Evaluation of the Bog Bird's-foot Trefoil, *Lotus pinnatus*, in Canada*

MARTA DONOVAN[1]

[1] Conservation Data Centre, British Columbia Ministry of Environment, Ecosystems Branch, P.O. Box 9993 Stn. Prov. Govt., Victoria British Columbia V8W 9R7 Canada.

Donovan, Marta. 2006. Conservation evaluation of the Bog Bird's-foot Trefoil, *Lotus pinnatus*, in Canada. Canadian Field-Naturalist 120(2): 157–162.

In Canada, Bog Bird's-foot Trefoil, *Lotus pinnatus*, is confined to vernally wet meadows, creek margins, ditches and seepages, where underground water comes to the surface. Seven localities, within a small area on the east coast of Vancouver Island near Nanaimo, British Columbia, have been confirmed in recent years. At two others it is considered extirpated. The lack of protection on private land, alterations to hydrology, and erosion arising from intensive recreational use of primary habitat by off-road vehicles as well as the appearance of invasive, species are the main concerns for British Columbia populations.

Key Words: Bog Bird's-foot Trefoil, *Lotus pinnatus*, endangered species, distribution, conservation, British Columbia.

Bog Bird's-foot Trefoil, *Lotus pinnatus* Hook†, is a low-growing, short-lived perennial of the pea family (Fabaceae) with many erect to spreading stems ranging from 15 to 60 cm long (Figure 1). The pinnately compound leaves are 4-8 cm long, with 5-9 elliptic, oblong or narrowly egg-shaped leaflets. The inflorescence is a compact, stalked, axillary umbel of 3 to 12 flowers. The corollas are 10-15 mm long with a yellow banner and keel and creamy-white wings. The keel petals are fused along one edge that is elongated into a well-defined beak towards the outside of the inflorescence. The calyx is tubular and lobed, with two upper lobes that are joined most of their length. The linear seed pods are 3-6 cm long and 1.5-2 mm wide and contain 5-20 cylindrical, glossy, dark-coloured seeds (Pojar 1999). In the field, several species superficially resemble *L. pinnatus*. Vetches (*Vicia* species) are often present in similar habitats, but the leaves are smaller than those of *L. pinnatus* and the terminal leaflet in *Vicia* spp. is a tendril. Seaside Birds-foot Trefoil (*Lotus formosissimus*) looks similar to *L. pinnatus* except the wing petals of *L. formosissimus* are pinkish-purple, while those of *L. pinnatus* are cream-colored. In addition, though a trifoliate bract usually subtends the flowers of *L. formosissimus*, bracts were sometimes absent in field specimens or only a unifoliate bract was present (Ryan and Douglas 1994*). *Lotus pinnatus* and *L. formosissimus* could be confused if the plants are immature or not in flower, but the two species do not overlap in their distribution in British Columbia. *Lotus formosissimus* is known only from the Victoria area and nearby islands, where it occurs in various xeric habitats, ranging from open grass-dominated meadows to exposed steep rocky sites with Garry Oak (*Quercus garryana*) (Ryan and Douglas 1994*). *Lotus pinnatus* is found only in the Nanaimo area on Vancouver Island, where it occurs in moist soil on exposed, coastal lowland areas. Bird's-foot Trefoil (*Lotus corniculatus*) could also be confused for *L. pinnatus* as it occasionally grows in wet places, but it is usually found in drier, disturbed sites. Also, *L. corniculatus* has completely yellow flowers and its leaflets are smaller and more blunt than the other trefoils.

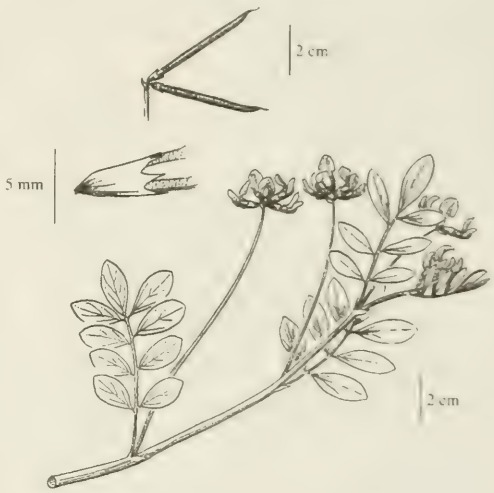

FIGURE 1. Illustration of *Lotus pinnatus* (line drawing in Hitchcock et al. 1961; Pojar 1999).

* The information, gathered during field surveys in 2003 formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Donovan 2004*) and the subsequent assessment of *Endangered* (COSEWIC 2004*). This paper includes more recent information that did not appear in the original status report.

† Taxonomy and nomenclature follow Douglas et al. (1999).

Distribution

Lotus pinnatus occurs in western North America from Vancouver Island, south to northwest Washington, western Oregon and the Columbia River Gorge, to central California and sporadically eastward to Idaho (Figure 2; Isely 1993; Pojar 1999). In Canada, *Lotus pinnatus* is known from seven extant populations within a small area on the east coast of Vancouver Island near Nanaimo (Donovan 2004*).

FIGURE 2. Distribution of *Lotus pinnatus* in North America (from Donovan 2004*).

Habitat

The British Columbia populations of *L. pinnatus* occur within the moist maritime subzone of the Coastal Douglas-fir (CDF) biogeoclimatic zone (Meidinger and Pojar 1991) in the Nanaimo Lowlands Ecosection of the Georgia Depression Ecoprovince (Demarchi 1996*). In this region, the Olympic Mountains in Washington State to the south and the Insular Mountains on Vancouver Island to the west produce a rain shadow effect resulting in a Mediterranean-type climate with warm, dry summers and mild, wet winters. Most of the rainfall occurs during the winter months, and limited precipitation and high temperatures during the summer months result in pronounced summer moisture deficits (Meidinger and Pojar 1991).

Lotus pinnatus grows in open, springy meadows, along the margins of creeks, or in seepages, where underground water comes to the surface and the plants are in close physical contact with cool, flowing water (H. Roemer, personal communication). In all cases, the soils are shallow (< 15 cm), over gently sloping sandstone or conglomerate bedrock with abundant moisture during the growing and blooming period. *Lotus pinnatus* is most commonly associated with Yellow Monkey-flower (*Mimulus guttatus*), Sea Blush (*Plectritis congesta*), White Triteleia (*Triteleia hyacinthina*), Small-leaved Montia (*Montia parvifolia*), Scouler's Popcornflower (*Plagiobothrys scouleri*) and American Speedwell (*Veronica beccabunga* ssp. *americana*). Stands of Douglas-fir (*Pseudotsuga menziesii*) and dense thickets of Nootka Rose (*Rosa nutkana*), Ocean Spray (*Holodiscus discolor*), Nine-bark (*Physocarpus capitatus*) and willow (*Salix* spp.) exist on the margin of some seepages but *Lotus pinnatus* does not occur in the shaded understory of these sites, suggesting that the species is shade-intolerant. Prolonged moisture, edge habitat along streams and meadows and shallow soils derived from sedimentary rock are key habitat components. Other factors, such as slope and aspect are variable and do not appear to be critical in defining suitable habitat. In British Columbia, the elevation for this species ranges between 40 m and 150 m.

Biology

Zandstra and Grant (1968) studied the biosystematics of native and introduced *Lotus* species in Canada and reported that although many of the Old World species are polyploids, none of the North American species examined exhibited the same trait. North American *Lotus* species have a base chromosome number of 6 or 7. Of the species native to Canada, *L. pinnatus* and *L. formosissimus* are considered to be the most closely related, based on morphological, habitat, and cytological characteristics. A chemotaxonomic study using thin-layer chromatography further supported the general relationships among Canadian *Lotus* species with *L. formosissimus* and *L. pinnatus* demonstrating the greatest degree of similarity (Grant and Zandstra 1968). These species differed from other native Canadian species in that both were perennial outcrossers with large flowers on long pedunculate umbels. The other three native species were self-fertile annuals with small flowers. Evolution in angiosperm reproduction has frequently occurred with a decrease in basic chromosome number, a shift from an outcrossing (cross-pollinating) to an inbreeding (self-pollinating) reproductive system and a shift from a perennial to an annual habit (Stebbins 1957). On this basis, Zandstra and Grant (1968) considered *L. pinnatus* and *L. formosissimus* to be more primitive than the annual species.

Lotus pinnatus germinates in the late winter or early spring when soil moisture and temperature conditions are most favourable, and seedling survival appears to be dependent on continuous surface moisture during this period. Though the specific timing of events will depend on local habitat conditions, flowering in *L. pinnatus* generally occurs between May and the end of June.

The pea-like, bisexual flowers are borne at the end of a long peduncle arising from the leaf axil, and the umbellate inflorescences are produced sequentially throughout the growing season. As the flowers senesce, some become progressively more reddish (Isely 1981). During July, when drought conditions are prevalent, seed maturation and dispersal begin, followed by die-back of the stems to the rootstock, which is located several centimetres below the soil surface. The seeds lack any strong adaptations for long-distance dispersal by wind or animal vectors. Most seeds are gravity-dispersed and generally land in the immediate vicinity of the parent plant. The plant's habitat along stream channels may permit the legumes and seeds to be transferred by water during times of seasonal flooding. However, germination and seedling survival appear to depend upon continuous surface moisture, and the species does not appear to be a strong competitor with native shrub species or with invasive alien plants. The chances of a healthy population returning to Canada if local populations become extirpated are highly unlikely. The nearest population in Washington State, from which collections were made in 1940, is 240 km away in Bremerton. Whether this population is extant is unknown.

As with other perennial species in the genus *Lotus*, Zandstra and Grant (1968) suggested that the flowers of *L. pinnatus* required cross-pollination to set viable seed. Given the bright yellow appearance of the flower and the wide keel that serves as a suitable landing platform, flowers of *L. pinnatus* appear to be adapted to bee pollination. Although the importance of the bumblebee to the flower (and vice versa) is yet to be specifically determined, bumblebees were observed visiting flowers of *L. pinnatus* at Harewood Plains during field observations made in 2003. Although bees are capable of dispersing pollen over short distances, cross-pollination between most populations in Canada is unlikely in view of the distances involved.

Like many other legumes, *L. pinnatus* appears to be associated with nitrogen-fixing *Rhizobium* bacteria that occupy root nodules and provide the plants with a source of reduced nitrogen in exchange for a supply of carbon and other nutrients. Specific strains of *Rhizobium* bacteria are required for effective nodulation of *Lotus* species grown as forage crops, such as *L. corniculatus* and *L. tenuis*. To maximize establishment in areas that have never produced *Lotus*, inoculation of seeds with the appropriate rhizobia is necessary (Blumenthal and McGraw 1999).

An examination of root nodules collected from *L. pinnatus* at Harewood Plains indicated the presence of bacteria, most likely of genus *Rhizobium* (S. Berch, personal communication).

Population Attributes

Lotus pinnatus has been reported from nine sites in British Columbia (Figure 3; Table 1), all in the Nanaimo area on Vancouver Island and on nearby Gabriola Island. Of the nine reported records, seven populations were verified in recent years. The remaining two sites have been extensively disturbed and it is unlikely that these populations currently exist. Between 1500 and 2000 individual plants were counted in Canada in 2003 over an area of 650 square metres. Relatively little is known of demographic characteristics and population trends of *L. pinnatus* due to a lack of long-term monitoring. Estimates of population trends in *L. pinnatus* are currently unreliable as the clumped, sprawling habit makes it difficult to identify separate individuals and counting methods have varied with different investigators. Until counting methods are standardized, population numbers should be considered rough estimates.

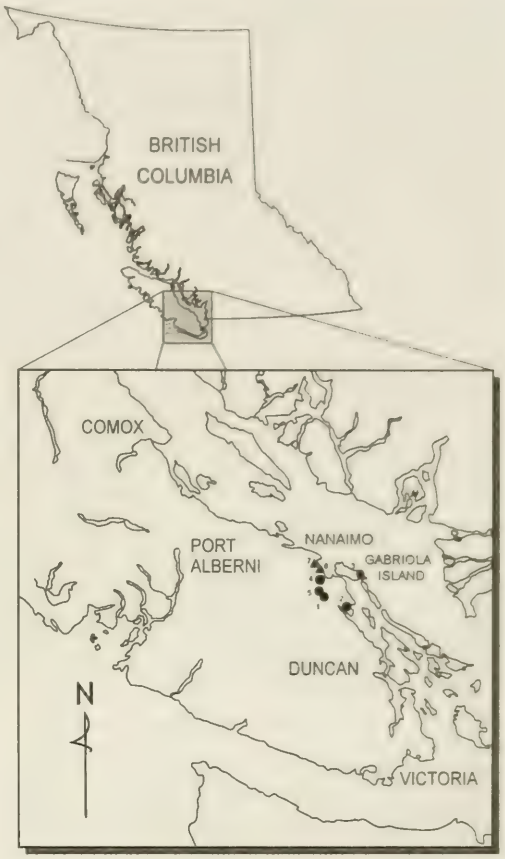

FIGURE 3. Distribution of *Lotus pinnatus* in British Columbia (from Donovan 2004*) ● confirmed; ▲ unconfirmed.

Provincial, National and Global Ranks

The British Columbia Conservation Data Centre has ranked *L. pinnatus* as "S1" and placed it on the "Red list". A rank of "S1" indicates that the species is "critically imperiled because of extreme rarity (often

* The collection by W. R. Carter at Mt. Benson in 1 June 1918 is included with this population as Harewood Plains may be considered the foothills of Mt. Benson.

5 or fewer occurrences) or because of factors making it especially vulnerable to extirpation." This is the most critical status that can be applied to a species at the provincial level. Though it currently lacks formal protection in British Columbia, *Lotus pinnatus* is a potential candidate for listing under the provincial *Wildlife Amendment Act* (2004).

At the national level, *Lotus pinnatus* has been assessed as Endangered by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC 2004*) and appears on Schedule 1 of the federal *Species At Risk Act* (Environment Canada 2006*).

Globally, *Lotus pinnatus* has a rank of G4G5 which indicates that the plant is apparently secure in most of its range (NatureServe Explorer 2006*).

Threats and Protection

Habitat loss presents a serious and urgent threat to *Lotus pinnatus* in Canada. Over 90% of the extant population of *L. pinnatus* is located on land that is privately owned, making this species vulnerable to habitat loss as a result of urban expansion and residential development.

In addition to potential commercial and residential development, the population of *L. pinnatus* at Harewood Plains is under direct and immediate threat of habitat degradation and fragmentation resulting from intensive, unauthorized use of recreational off-road vehicles; including ATVs, 4 × 4s and dirt bikes (C. Thirkill, personal communication). In some areas at this site, the thin and fragile soils have been rutted down to bedrock and plants have been dislodged on to bare rock where they cannot re-establish (Figure 4). There is high potential for further impacts as vehicles continue to access the site, despite efforts by the former landowner (Weyerhaueser Canada) to block access to off-road vehicles with boulder placements, ditches and the installation of several cement barriers along the access road (C. Thirkill, personal communication). In an effort to minimize the disturbance of sites designated as "Environmentally Sensitive Areas" the City of Nanaimo has established a Development Permit Area on a portion of the property at Harewood Plains (Rob Lawrance, personal communication). As the habitat at Harewood Plains supports several other species at risk such as Dense-spike Evening Primrose (*Epilobium densiflorum*), Green-sheathed Sedge (*Carex feta*), Foothill Sedge (*Carex tumulicola*), Slim-leaf Onion (*Allium amplectens*) and Nuttall's Quillwort (*Isoetes nuttallii*), a working group comprised of representatives from industry, non-governmental organizations and local and provincial governments has been established in order to develop proactive communication with the different land owners, managers and stakeholders at this location.

At the site south of Extension, near Nanaimo, at least some portions of the population have been reported extirpated due to recreational off-road vehicle use and residential development (A. Ceska, personal communication).

Other than habitat destruction, competitive exclusion from native and non-native vegetation represents the most significant ongoing threat to *L. pinnatus* at all sites. Encroachment of native shrub species in potential habitats may prevent this species from occupying new sites. Invasive alien grass species that threaten the persistence of *L. pinnatus* include Sweet Vernalgrass (*Anthoxanthum odoratum*), Orchard Grass (*Dactylis glomerata*), Kentucky Bluegrass (*Poa pratensis*) and Barren Brome (*Bromus sterilis*). Scotch Broom (*Cytisus scoparius*) is the most dominant invasive alien shrub. Logging operations close to (within 50 m of) populations of *L. pinnatus* at Harewood Plains increase the potential for the spread of aggressive native and non-native plant species. By disturbing soils and carrying seeds, off-road vehicles are also a major factor in the spread of invasive non-native plants in sensitive areas.

The population located in the Woodley Range Ecological Reserve is protected, to a certain extent, by its

FIGURE 4. Destruction of habitat caused by all-terrain vehicles at Harewood Plains (Photo George Douglas, 2003).

location within an ecological reserve, but this represents only 7% of the total Canadian population. In addition, plants at this location are vulnerable to adjacent land uses including all-terrain vehicle use, logging and other land clearing activities which could impact on the hydrological features that provide seepage to the location.

A national multi-species strategy that addresses the recovery of *Lotus pinnatus* and five other endangered plant species of vernal pools and other ephemeral wet areas has been completed. This strategy outlines recovery goals for each species, suggests strategic approaches for meeting the recovery goals and recommends that a draft recovery action plan (RAP) be completed by October 2009, which includes proposing Critical Habitat for this species under the *Species At Risk Act* (Parks Canada Agency 2005*).

Evaluation

The British Columbia Conservation Data Centre considers *Lotus pinnatus* to be endangered in British Columbia (Donovan 2004*) and the Committee on the Status of Endangered Wildlife in Canada has assessed the species as Endangered (COSEWIC 2004*). Only a few small fragmented populations remain, and these are restricted to wet meadows of limited occurrence that are considerably disjunct from the main range of the species in the north-western United States. The populations are at risk from continued habitat loss, encroachment of invasive species and recreational off-road vehicle use. Development of the habitat supporting the only sizeable remaining population could result in significant losses to the population (COSEWIC 2004*).

Acknowledgments

Thanks to Jenifer Penny, Charles Thirkill and Don Piggott for help with field surveys. Hans Roemer and Shannon Berch provided information and technical assistance. Matt Fairbarns provided strong support throughout this study and Ted Lea reviewed the manuscript. I am indebted to the late George Douglas for nurturing my interest in plants.

Douglas, George W., Jenifer L. Penny, and Ksenia Barton. 2006. Conservation evaluation of the Pacific Population of Dwarf Woolly-heads, *Psilocarphus brevissimus* var. *brevissimus*, in Canada. Canadian Field-Naturalist 120(2): 163–168.

In Canada, Dwarf Woolly-heads, *Psilocarphus brevissimus* var. *brevissimus*, is restricted to the Similkameen River valley, south of Princeton in southwestern British Columbia and the extreme southeast and southwest corners of Alberta and Saskatchewan, respectively. This paper deals with the three British Columbia populations which represent the northwestern limit of the species which ranges from south-central British Columbia, southward in the western United States to Montana, Idaho, Washington, Oregon, Nevada, Utah, Wyoming , California and Baja California, Mexico. In British Columbia, *P. brevissimus* is associated with calcareous vernal pools and ephemeral pond edges in large forest openings. This habitat is rare in the area the few existing populations could easily be extirpated or degraded through slight changes in groundwater levels, coalbed methane gas drilling, housing development or recreational vehicles.

Key Words: Dwarf Woolly-heads, *Psilocarphus brevissimus* var. *brevissimus*, British Columbia, endangered, distribution, population size.

Dwarf Woolly-heads, *Psilocarphus brevissimus* var. *brevissimus* Nutt.†, is a member of a genus of five species which occur in the Americas (Cronquist 1950). It is one of three species occurring in British Columbia and Canada (Douglas 1998). Two varieties of *P. brevissimus*, var. *brevissimus* and var. *multiflorus*, are recognized. The var. *multiflorus* occurs only in California (Morefield 1993). *Psilocarphus brevissimus* var. *brevissimus* was first recorded in Canada in 1997 (Douglas et al. 1998a).

Psilocarphus brevissimus var. *brevissimus* is a prostrate, matted annual herb with a short taproot (Figure 1; Douglas 1998). The plants are from 8 to 20 cm long. The few leaves are restricted to the stems and are opposite, lance-linear to lance-oblong or lance-triangular, 4-15 mm long and white woolly-hairy. The flower heads are disciform, lack a pappus, and are usually solitary in the leaf axils or at the tips of the branches and lack involucres. The receptacular bracts are 2.4-4 mm long, hooded and balloonlike. The achenes are more or less cylindric, glabrous, nerveless and tipped with a small, 1-2 mm long, offset style.

In British Columbia herbaria, specimens of *P. brevissimus* var. *brevissimus* may be distinguished from *P. elatior* by their prostrate and matted habit and much narrower leaves. It is separated from *P. tenellus* var. *tenellus* by its longer (2.5-4 mm versus 1.3-2.5 mm

FIGURE 1. Illustration of *Psilocarphus brevissimus* var. *brevissimus* (Line drawing by Elizabeth J. Steven in Douglas et al. 1998; 2002a).

* The field work for *Psilocarphus brevissimus* was funded by the British Columbia Conservation Data Centre. The results appear in the British Columbia Conservation Data Centre database and a rare plant manual (Douglas et al. 2002). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Douglas et al. 2003*) and the subsequent assessment of *Endangered* (COSEWIC 2003*). This paper includes more recent information that did not appear in the original status report.

† Taxonomy and nomenclature follows Douglas et al. (1998b; 1998c; 1999; 2001).

TABLE 1. Locations and population sizes for *Psilocarphus brevissimus var. brevissimus* south of Princeton, British Columbia.

Collection site	Observation	Collector/Observer	Number of plants/area
Princeton, Tracey Lake, ca. 0.75 km SE of Lake	1996	Lomer	30/unknown
Princeton, Tracey Lake, ca. 1.3 km ESE of Lake	2002	Douglas and Penny	450/392 m^2
	2004	Douglas and Smith	7200±500/100 m^2
Princeton, Stevenson Lake, ca. 0.75 km SE of	2002	Douglas and Penny	900 000±100 000/570 m^2
	2004	Douglas and Smith	11 775/155 m^2

long) receptacular bracts and its much narrower leaves. For many years in Alberta and Saskatchewan, this species was called *P. elatior* (Packer 1983; Kershaw 2001; Saskatchewan Conservation Data Centre 2004*). In 2004, Alberta taxonomists examined material from both provinces and reidentified them as *Psilocarphus brevissimus* var. *brevissimus* (J. Gould, personal communication). It is quite likely that the "species of concern" ranking given by COSEWIC (2004*) for the Alberta/Sackatchewan populations of *P. elatior* will now be applied to the *P. brevissimus* populations.

North American and Provincial Ranges

Psilocarphus brevissimus var. *brevissimus* ranges from south-central British Columbia, southward in the western United States to Montana, Idaho, Washington, Oregon, Nevada, Utah, Wyoming, California and Baja California, Mexico (Morefield 1993; Cronquist 1994; Douglas 1998). There are also disjunct populations in Chile and Argentina (Cronquist 1950, 1955). In Canada, the species is known only from along 2.6 km of Highway #3 in the Similkameen River valley south of Princeton in south-central British Columbia (Figure 2; Douglas 1998; Douglas et al. 2002) and in the south-eastern and south-western corners of Alberta and Saskatchewan, respectively.

Habitat

Psilocarphus brevissimus var. *brevissimus* occurs in the southern interior of British Columbia in the lower montane zone in the Interior Douglas-fir biogeoclimatic zone (Hope et al. 1991). Climatic conditions are continental, characterized by hot, dry summers, a fairly long growing season and cool winters. A rain-shadow effect prevails in this area due to the presence of the Coast-Cascade Mountains to the west.

Within this zone, the sites occur in a matrix of level to gently sloping Big Sagebrush (*Artemisia tridentata*) shrub/grassland with scattered Ponderosa Pine (*Pinus ponderosa*) and Douglas-fir (*Pseudotsuga menziesii*) [Nomenclature follows Douglas et al. 1998, 1998c, 1999 and 2001]. The area is at the western edge of the distribution of open shrub/grassland at that elevation. Specifically, *P. brevissimus* var. *brevissimus* occurs in calcareous clay soils in vernal pools in large forest openings dominated by Scouler's Popcornflower (*Plagiobothrys scouleri*) and Close-flowered Knotweed (*Polygonum polygaloides* ssp. *confertiflorum* (Figure 3). Associates in these sites include One-spike Oat-grass (*Danthonia unispicata*), Tiny Mousetail (*Myosurus minimus*), Carolina Meadow-foxtail (*Alopecurus carolinianus*), Common knotweed (*Polygonum aviculare*), Lowland Cudweed (*Gnaphalium palustre*), and Annual Hairgrass (*Deschampsia danthonioides*). *Psilocarphus brevissimus* var. *brevissimus* also occurs at the edge of ephemeral ponds in the same type of substratum (Figure 4). The vernal pools and ephemeral pond edges are wet in spring and dry and compacted in the summer.

Psilocarphus brevissimus var. *brevissimus* is considered to be a vernal pool specialist (Schlising and Sanders 1982; Keeley and Zedler 1998; Bauder 2000). Keeley and Zedler (1998) define vernal pools as "precipitation-filled seasonal wetlands inundated during periods when temperature is sufficient for plant growth, followed by a brief waterlogged-terrestrial stage and culminating in extreme desiccating soil conditions of extended duration". The species is able to outcompete grassland species due to its tolerance of inundation, and aquatic/wetland species due to its tolerance of soil dessication and heat during summer drought (Bauder 2000).

Biology

Little information is available on the biology of *Psilocarphus brevissimus* var. *brevissimus* in British Columbia. Only basic facts about its life cycle and reproduction are known.

Keeley and Zedler (1998) recognize four stages in the annual vernal pool cycle: (1) a wetting phase; (2) an aquatic or inundation phase; (3) a waterlogged-terrestrial phase; and (4) the drought phase. In vernal pool species, germination is typically initiated during the wetting or inundation phases. Flowering is usually initiated during the transition to the waterlogged-terrestrial phase. In the Princeton area of south-central British Columbia, this phase occurs during June and fruiting follows in July during the drought period.

Psilocarphus brevissimus var. *brevissimus* is an annual herb that likely reproduces primarily by self-pollination. The assumption of a selfing breeding system is based on the taxon's lack of pollinator attracting structures and the proximity of the stigmas to the central pollen-producing flowers. In addition, the abundance of woolly hairs and lack of achene pappus appear to limit pollen dispersal by wind. Another possibility is that plants set seed without pollination, through asexual reproduction (Cronquist 1950).

Animals may be the primary vectors of seed dispersal for *Psilocarphus brevissimus* var. *brevissimus*. Birds may disperse seeds over small and large geographic areas. The use of vernal pools by various migrating avian species, particularly waterfowl and shorebirds, is well documented in other regions (Silveira 1998). Finally, cottontail rabbits (*Sylvilagus spp.*) are potential agents of dispersal of *P. brevissimus* var. *brevissimus* seeds. A study in California found that *P. brevissimus* var. *brevissimus* seeds were commonly found in cottontail rabbit pellets. The excreted seeds germinated easily, suggesting that the lagomorphs may be important agents of seed dispersal between vernal pools on a small scale (Zedler and Black 1992). British Columbia sites for *P. brevissimus* var. *brevissimus* may provide habitat for Nuttall's Cottontail (*Sylvilagus nuttallii*), a species that frequents grasslands.

Population Attributes

The three populations of *Psilocarphus brevissimus* var. *brevissimus* were discovered in 1997 in the Similkameen River valley, west of Princeton, British Columbia (Table 1; Douglas et al. 1998a). These populations are between approximately 0.8 and 2.6 km apart (Figure 2). During the period from 2002 to 2004, two of the populations decreased in size by about 25%. Plant numbers increased at one site from 450 to about 7200 plants and decreased at the other from about 900 000 to about 12000 plants.

Trends for these populations are not well known but it is obvious that they can be expected to vary markedly due to differences in yearly seed germination and seedling success. Population sizes of this annual herb are strongly tied to annual precipitation patterns (Bauder 2000) and are typical of vernal pool plants (Griggs and Jain 1983).

Provincial, National and Global Ranks

Globally, *Psilocarphus brevissimus* var. *brevissimus* has a rank of G4T4 indicating that in most of its range the plant is secure and frequent to common. Since the species is restricted to British Columbia it has a national rank in Canada of N1. Provincially, *P. brevissimus* var. *brevissimus* has been ranked S1 by the Conservation Data Centre and appears on the British Columbia Ministry of Sustainable Resource Management red list (Douglas et al. 2002). This is the most critical rank that can be applied to species at the provincial level and indicates that the species is "critically imperiled because of extreme rarity (typically five or fewer occurrences or very few remaining individuals) or because of some factor(s) making it especially vulnerable to extirpation or extinction".

Threats and Protection

The major threats to *P. brevissimus* var. *brevissimus* are through drilling for coalbed methane gas, housing development and off-road recreational vehicles. In 2002

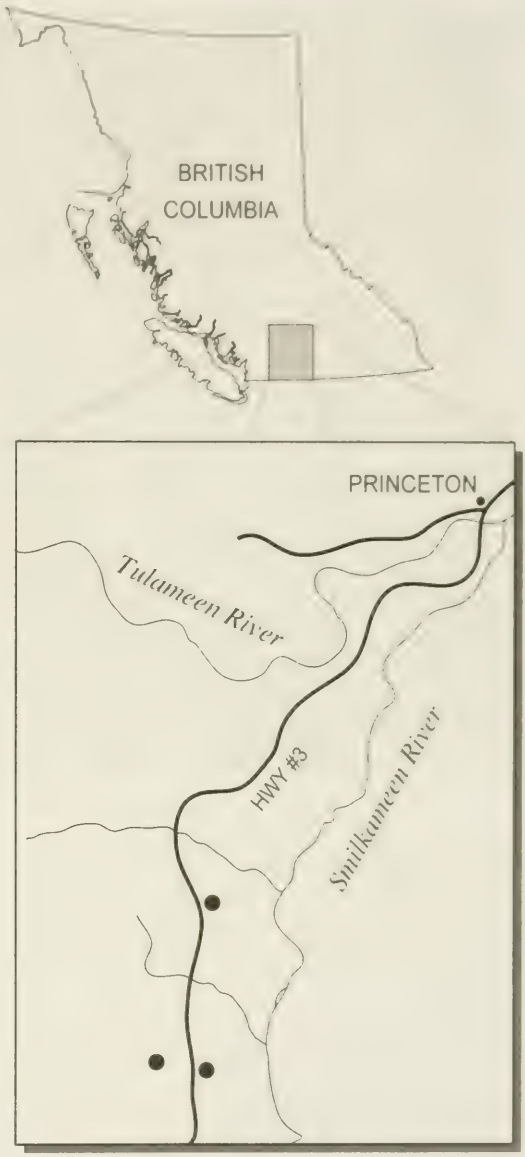

FIGURE 2. Distribution of *Psilocarphus brevissimus* var. *brevissimus* in British Columbia.

three test holes, targeting coalbed methane gas deposits, were drilled in the Similkameen valley. If brought into production the drilling, access roads and pumping stations could cause major degradation in the area.

Other potential threats result from activities that are permitted in the Agricultural Land Reserve. The private property where *P. brevissimus* var. *brevissimus* occurs is on the Agricultural Land Reserve, where primary land use is agriculture. For instance, some types of fill/soil removal are allowable without application to the Agricultural Land Commission (Provincial Agri-

FIGURE 3. Calcareous vernal pool habitat of *Psilocarphus brevissimus* var. *brevissimus* south of Princeton, British Columbia. Colorado Rush (*Juncus confusus*), another rare species in British Columbia, is conspicuous on both sides of the dried-up vernal pool. The several large plants in the habitat are the introduced grass, American Sloughgrass (*Beckmannia syzigachne*).

cultural Land Commission 2003*). On these lands, development pressures do not appear to be an immediate issue at this time. The Agricultural Land Reserve status may prevent subdivision development, but does allow other activities that could also potentially threaten the populations. In recent years many tracts of Agricultural Land Reserve land in southern British Columbia has been converted to housing developments, shopping malls and golf courses, either by decisions of the Agricultural Land Commission or very rarely by an "order in council" by the sitting provincial legislature.

Another threat likely to have a negative impact is recreational off-road vehicle use. The authors observed evidence of all-terrain vehicles and dirt bike use in the area of the sites in 2004. The vernal pools and ephemeral pond edges are wet in spring and are susceptible to permanent changes if disturbed at this.

An additional threat to the population of *P. brevissimus* var. *brevissimus* is its vulnerability to extirpation due to the extremely small occupied area and population size. Such small populations are at risk of inbreeding depression (Primack 1998). Due to lack of genetic variation, these small populations are vulnerable to demographic and environmental variation. Furthermore, suitable habitats for *P. brevissimus* var. *brevissimus* in the southern interior of British Columbia are extremely limited and thus opportunities for colonisation are also limited.

Psilocarphus brevissimus var. *brevissimus* is not formally protected in British Columbia, however, it could be in the future since this species is a potential candidate for listing under the provincial *Wildlife Amendment Act* (2004). As part of its commitment to the National Accord (*National Accord for the Protection of Species at Risk*), the province is required to take measures to protect this species. It is on Schedule 1 of the federal *Species At Risk Act* and a recovery strategy is expected to be completed by the summer of 2006.

Evaluation

The British Columbia Conservation Data Centre considers *P. brevissimus* var. *brevissimus* to be threatened/endangered in British Columbia (Douglas et al. 2002) and the Committee on the Status of Endangered Wildlife in Canada has assessed the species as endangered (COSEWIC 2003*). The three populations are small and vulnerable to a number of threats. With limited knowledge of the plant's biological and ecological requirements, this species is vulnerable to extirpation in British Columbia. Without research on growth requirements and further demographic information, the stability of the present populations will remain unknown. The limited number of plants also reduces the potential for genetic variation, which may be necessary to respond to environmental changes in the future.

Acknowledgments

We thank Frank Lomer for providing information on his original discovery of *Psilocarphus brevissimus* var. *brevissimus* in 1997 and for his assistance in relocating the sites in 2002. Shyanne J. Smith assisted with field work in 2004.

Conservation Evaluation of Pacific Rhododendron, *Rhododendron macrophyllum*, in Canada*

GEORGE W. DOUGLAS[1] and JULIE DESROSIERS[2]

[1] Deceased.
[2] 4254 Garden Drive, Burnaby, British Columbia V5G 4G6 Canada

Douglas, George W., and Julie Desrosiers. 2006. Conservation evaluation of Pacific Rhododendron, *Rhododendron macrophyllum*, in Canada. Canadian Field-Naturalist 120(2): 169–174.

In Canada, Pacific Rhododendron (*Rhododendron macrophyllum*) is restricted to the Skagit River drainage and southeastern Vancouver Island in southwestern British Columbia. These populations represent the northern limits of the species, which ranges south to northern California. In British Columbia, *Rhododendron macrophyllum* is usually associated with coniferous forests. Until recently this species was considered to be rare. Results of this study indicate that the populations in the Skagit River watershed are large, extensive and mostly contained in protected areas, thus the species is not considered to be at risk in Canada at this time.

Key Words: Pacific Rhododendron, *Rhododendron macrophyllum*, distribution, conservation evaluation, British Columbia

The Pacific Rhododendron, *Rhododendron macrophyllum* D. Don *ex* G. Don†, is a member of a genus of almost 1000 species occurring mainly in northeastern Asia (Wallace 1993). It is one of three species occurring in British Columbia (Meidinger 1999) and four occurring in Canada (Scoggan 1979).

Rhododendron macrophyllum was first reported by naturalist Archibald Menzies in 1792 in his "Journal of Vancouver's Voyage", and subsequently described by David Don in 1834. Joseph Hooker also described plants collected during Vancouver's voyages, and in 1855 he published a description of this rhododendron under the species name *californicum*. This name was in common use by botanists for close to a century.

Rhododendron macrophyllum is an erect to spreading, branched shrub, 1-8 m tall (Meidinger 1999; Figure 1). The evergreen leaves are alternate, often appearing whorled, ovate or elliptical, 8-20 cm long, 3-6 cm wide, leathery, dark green above, paler beneath and glabrous, or nearly so. The pale-pink to deep rose-purplish corollas are tubular bell-shaped, spotted red-brown and 2.5-4 cm long and up to 5 cm across. The fruits consist of woody capsules 1.5-2 cm long with numerous minute seeds. It is easily separated from the other two *Rhododendron* species in British Columbia. Lapland Rosebay (*Rhododendron lapponicum*) is a northern plant with much shorter habit and smaller leaves, while White-flowered Rhododendron (*R. albiflorum*) is a higher elevation species with white flowers.

North American and Provincial Ranges

Rhododendron macrophyllum is restricted to coastal habitats from northern California north through Oregon and Washington to southwestern British Columbia (Hitchcock et al. 1959). In Canada, it occurs in southwestern British Columbia in the western Cascade Mountains (Skagit River valley) and on southeastern Vancouver Island (Shawnigan and Rhododendron lakes) [Meidinger 1999; Douglas et al. 2002; Figure 2].

Habitat

Skagit River Valley

The *Rhododendron macrophyllum* populations in the Skagit River valley occur on well-drained, coarse-textured, gravelly, dry soils overlain by fibremors. Elevations range from 500 to 870 metres.

About half of the *Rhododendron* populations in the Skagit River valley are within the Interior Douglas-fir (IDF) Zone while the remaining are within the Coastal Western Hemlock (CWH) Zone (Hope et al. 1991; Pojar et al. 1991). Summaries of all plant communities within these zones are taken from Desrosiers and Cadrin (1993*). The four plant communities within the Interior Douglas-fir (IDF) Zone are described below:

(a) Douglas-fir/Falsebox/Feathermoss (*Pseudotsuga menziesii Paxistima myrsinites/Pleurozium schreberi*) community.

Sites for this community are located in the dry, middle part of the Skagit River Valley, on the flats of the

* The field work for the *Rhododendron macrophyllum* project was funded by the British Columbia Conservation Data Centre and The Skagit Environmental Endowment Commission. The results appear in the British Columbia Conservation Data Centre database and a Skagit Environmental Endowment Commission report (Desrosiers and Cadrin 1993*). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Desrosiers and Douglas 1997*) and the current assessment of *not at risk* (COSEWIC 2006*).

† Taxonomy and nomenclature follows Douglas et al. (1998a, 1998b, 1999a, 1999b, 2000, 2001) and Schofield (1992).

FIGURE 1. Illustration of *Rhododendron macrophyllum*. (Line drawing by Lora May Richards)

valley floor. These are the driest IDF sites and were mid-range in terms of their nutrient regime. The 80-115 year old stands are dominated by *Pseudotsuga menziesii, Paxistima myrsinites*, and *Pleurozium schreberi*. Other important species include *Rhododendron macrophyllum,* Lodgepole Pine (*Pinus contorta),* White Hawkweed (*Hieracium albiflorum),* Heart-leaved Twayblade (*Listera cordata)* and Cow-wheat *(Melampyrum lineare* var. *lineare). Rhododendron macrophyllum* had an average cover of 27% in this community.

(b) Douglas-fir – Western Redcedar/Beaked Hazelnut (*Pseudotsuga menziesii-Thuja plicata/Corylus cornuta)* community.

The lowest elevations in the lower part of the valley contained these sites. They tended to be intermediate, both environmentally and floristically, for the IDF in this area. *Pseudotsuga menziesii, Thuja plicata,* and *Corylus cornuta* were dominants in these 80-100 year old stands. Cover values for *Thuja plicata,* Western Hemlock (*Tsuga heterophylla), Paxistima myrsinites*

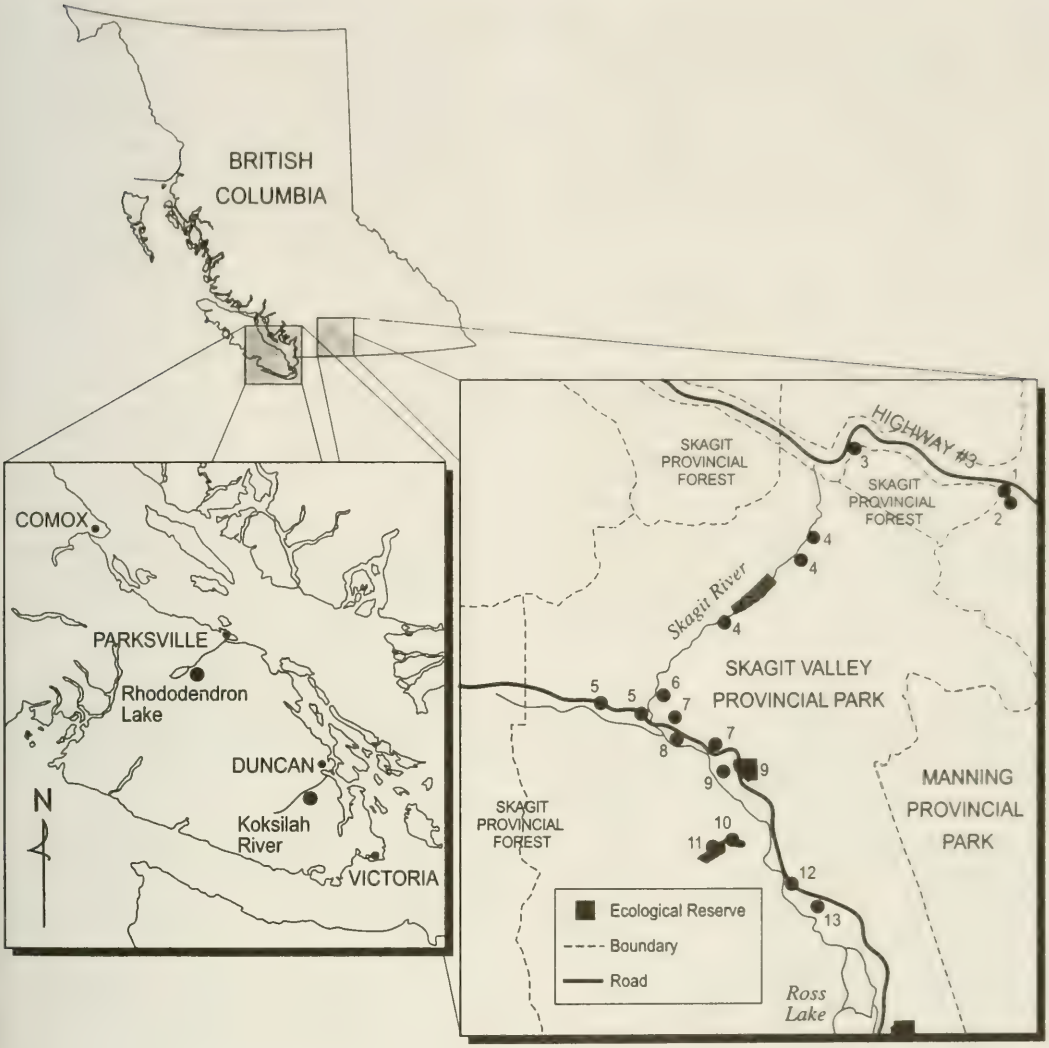

FIGURE 2. The location of *Rhododendron macropyhllum* sites in British Columbia.

and Dull Oregon-grape *(Mahonia nervosa)* were highest in these sites. Average cover of *Rhododendron macrophyllum* was 3%.

(c) Douglas-fir – Western Redcedar/Vine Maple *(Pseudotsuga menziesii-Thuja plicata/Acer circinatum)* community.

This community is found at a higher elevation than other IDF sites, on the east-facing slopes of the Rhododendron Ecological Reserve. The sites were mid-range in term of moisture regime and were nutrient-poor. *Pseudotsuga menziesii, Thuja plicata, Acer circinatum* and Step Moss (*Hylocomium splendens)* were the dominant species. Douglas Maple (*Acer glabrum* var. *douglasii),* Thimbleberry *(Rubus parviflorus* var. *parviflorus),* Oceanspray (*Holodiscus discolor),* Hooker's Fairybells (*Prosartes hookeri* var. *oregana*), Fireweed (*Epilobium angustifolium),* and Lanky Moss *(Rhytidiadelphus loreus)* were also important. *Rhododendron macrophyllum* had an average cover of 3%.

(d) Pacific Rhododendron/Western Tea-berry/Cladonia (*Rhododendron macrophyllum/Gaultheria ovatifolia/Cladonia)* community.

This *Rhododendron* community occurs on the eastern section of the Rhododendron Ecological Reserve as well as on the west side of the Skagit River. These sites were among the driest and most nutrient-poor of all sites sampled. The stands were 105-115 years old.

Tree cover in these plots was extremely low. *Pseudotsuga menziesii* had an average cover of 8% while Western White Pine (*Pinus monticola)* had an average cover of 7%. Average cover of *Rhododendron macrophyllum* was the highest of all plots at 70%. Species of importance in this community included Soopolallie (*Shepherdia Canadensis), Paxistima myrsinites,* Twinflower (*Linnaea borealis), Mahonia nervosa,* Kinnikinnick (*Arctostaphylos uva-ursi)* and species of lichen (*Cladonia* spp.).

All of the plots sampled in the northern half of the study area fell within a single community type in the Coastal Western Hemlock (CWH) Zone. This community may be summarized as follows:

Douglas-fir – Western Hemlock/Falsebox (*Pseudotsuga menziesii-Tsuga heterophylla/Paxistima myrsinites)* community.

Compared to IDF sites the CWH sites have higher moisture regimes, lower nutrient levels and higher tree cover values. In addition to *Pseudotsuga menziesii, Tsuga heterophylla* and *Paxistima myrsinites* other important species include Amabilis Fir (*Abies amabilis),* Grouseberry (*Vaccinium scoparium)* and *Hylocomium splendens*. The stands ranged from 80-150 years old. Average cover of *Rhododendron macrophyllum* was 18%.

Southeastern Vancouver Island

The *Rhododendron* sites on southeastern Vancouver Island are within the Coastal Douglas-fir Zone (Neuzdorfer et al. 1991). The populations east of Shawnigan Lake were found in the following plant community:

Western Redcedar/Pacific Rhododendron-Alaskan Blueberry/Step Moss (*Thuja plicata/Rhododendron macrophyllum-Vaccinium alaskense/Hylocomium splendens)* community.

This community was located on a moderate, southwest slope at an elevation of 490 m approximately 16 km west of Shawnigan Lake. The small (550 m^2) area on which *Rhododendron* occurred was dominated by 40 m tall *Thuja plicata*. The shrub layer was well-developed with *Rhododendron macrophyllum, Vaccinium alaskense,* Red Huckleberry *(V. parvifolium)* and Salal (*Gaultheria shallon)* dominating. A dense layer of mosses and lichens was dominated by *Hylocomium splendens*.

At Rhododendron Lake three markedly different communities occur in bands around Rhododendron Lake. A very wet band of vegetation (about 3-5 m wide), dominated mainly by Sweet Gale (*Myrica gale),* occurs around the immediate edge of the lake. Adjacent to the latter band is another, slightly drier but still very moist 3-10 m band of vegetation containing *Myrica gale* and *Rhododendron macrophyllum*. This saturated habitat is atypical for *Rhododendron macrophyllum*. A wider band (5-25 m wide) of forested vegetation occurs upslope from the lakeside communities. Approximately nine ha was covered by *Rhododendron* plants in the latter two vegetation bands. The two communities containing *Rhododendron* may be summarized as follows:

(a) Pacific Rhododendron – Sweet Gale/Salal (*Rhododendron macrophyllum-Myrica gale/Gaultheria shallon)* community.

This community occurs in a 3-10 m wide band that extends for about 300 m along the south side of the lake. Soils are constantly wet with the presence of Skunk Cabbage (*Lysichitum americanum)* and *Sphagnum* sp. indicating the hydric nature of the site. This site had been logged many years earlier. It appears all trees cut were Yellow-cedar (*Chamaecyparis nootkatensis)* and would have had about a 40-60% average cover. At the present time, *Rhododendron macrophyllum* has an average cover of 47% with only *Gaultheria shallon* being more abundant (average cover of 57%). Bracken Fern (*Pteridium aquilinum),* Labrador Tea (*Ledum groenlandicum)* and *Myrica gale* were also important species in the community.

(b) Western Hemlock/Pacific Rhododendron/Salal (*Tsuga heterophylla/Rhododendron macrophyllum/Gaultheria shallon)* community.

Upslope from the previous community is a forested community dominated by *Tsuga heterophylla*. The site has been partially logged and was previously dominated by *Thuja plicata*. Other coniferous species present, but in low numbers, include *Chamaecyparis nootkatensis, Thuja plicata, Pinus monticola* and *Pseudotsuga menziesii*. Important understory species include *Gaultheria shallon, Rhododendron macrophyllum* and *Hylocomium splendens*. *Rhododendron* has an average cover of 61%.

Biology and Ecology

Research on the biology and ecology of *Rhododendron macrophyllum* has been limited. The majority (60%) of populations in the Skagit Valley showed good to very good vigour. One in three populations had young genets less than one metre in height. These appear, for the most part, to have germinated on rotten logs or thick moss mats. Asexual reproduction, by layering, appears to be much more common than sexual reproduction.

Many sites showed evidence of fire on the dominant trees and charcoal layers were often found in the soil profile. This history of fire and its importance to the maintenance of *Rhododendron macrophyllum* populations was also noted in an Olympic National Forest study (Henderson et al. 1989).

Population Attributes

Approximately 200 populations of *Rhododendron macrophyllum* have been observed at 15 ecosites in the Skagit River valley over a distance of 25 km (Figure 2). Of these, 92 were examined in detail at 13 ecosites for this study (Table 1). Populations ranged in size from 4 m^2 to about 200 000 m^2. The latter area (part of the Rhododendron Ecological Reserve) had an extrapolated count of approximately a million canes. Two populations on Vancouver Island were also examined. Counts at one of them (Rhododendron Lake) revealed 400 plants and approximately 9000 canes.

TABLE 1. Locations and population sizes of *Rhododendron macrophyllum* in south-western British Columbia

Map Location Number(s)/ Ecosite Name	Number of Populations	Approximate Area of Populations (m^2)	Approximate Total Number of Canes
Manning Provincial Park			
1. Cayuse Flats	1	300	1 000
2. Silverdaisy Trail	3	250	1 750
3. Rhododendron Flats	4	150	2 400
Skagit Valley Provincial Park			
4. Upper Skagit Area	3	12	600
5. Klesilkwa River	6	360	600
6. Valley Floor North	2	400	2 100
7. *Pinus contorta* Terrace North	53	3 450	no count
8. *Pinus contorta* Terrace South	4	920	4 000
9. Shawatum Area	4	140	300
10. Rhododendron Ecological Reserve, East	1	200 000	1 000 000
11. Rhododendron Ecological Reserve, West	3	40	550
12. Nepopekum area	6	60	1 000
13. Galene Lakes Trail	3	100	1 250
Vancouver Island			
1. Rhododendron Lake	1	90 000	9 000
2. Shawnigan Lake	1	550	no count

[1] Detailed counts of canes per plant were made for 50 plants at both Cayuse Flats and Rhododendron Lake. Numbers of canes per plant ranged from 18 to 24 at Cayuse Flats and 20 to 25 at Rhododendron Lake (Desrosiers and Douglas 1997*).

The intensive inventory work conducted by the British Columbia Conservation Data Centre resulted in the documentation of thousands of plants in the Skagit Valley (Table 1). Prior to this work the species had been reported as a rare plant in British Columbia (Straley et al 1985; Argus and Prior 1990).

Locations of *Rhododendron macrophyllum* in the nearby Chilliwack River valley were mentioned by Slaney (1971*); however, no references or supporting information were provided in that document. It is possible that these populations could be extirpated due to development. In addition, *Rhododendron macrophyllum* was reported from Lightning Lake in Manning Park (Carl et al. 1952); this population was not verified by the authors or others working in that area.

Provincial, National and Global Ranks

Provincially *R. macrophyllum* is ranked S4 (Douglas et al. 2002) which indicates that it is "rare or uncommon (typically 21 to 100 occurrences); may be susceptible to large-scale disturbances; e.g., may have lost extensive peripheral populations". Since the species is restricted to British Columbia, the National rank is N1. Globally, *Rhododendron macrophyllum* is ranked G5. This ranking indicates that, on a global scale, the plant is considered "frequent to common or very common; demonstrably secure and essentially ineradicable under present conditions".

Threats and Protection

Habitat destruction, due to logging and road building, likely eliminated some populations of *Rhododendron macrophyllum*, especially in the Skagit River area. The establishment of Manning Provincial Park and the more recent Skagit Valley Provincial Park has eliminated most threats to *R. macrophyllum*. On Vancouver Island, where the two populations are located within timber harvesting areas, small informal protected areas have been established.

In the Skagit River valley it was evident that fire had previously swept through most of the ecosites (Desrosiers and Cadrin 1993*). Whenever possible, natural fires are quickly extinguished in the Cascades Mountains. If this control is successful over long periods of time, fuel loads may build up resulting in extremely hazardous conditions. It is, therefore, possible that population sizes may be temporarily reduced from time to time after large burns.

Rhododendron macrophyllum receives protection since all but the Vancouver Island populations occur in provincial parks. The Vancouver Island populations have informal protection set up by the timber companies that own the properties

Until recently there was formal protection under the *Dogwood, Rhododendron and Trillium Protection Act*. This act was repealed in 2002 due to our greater knowledge of the abundance of the species involved and the fact that sufficiently large numbers of their populations occur in protected areas.

Evaluation

Rhododendron macrophyllum was considered rare in Canada for many years (Straley et al. 1985; Argus and Pryor 1990). The present study, however, indicates that the species is not rare and is much more abundant than previously thought. Most of the extant sites

are secure since they are contained either within E. C. Manning Provincial Park, the adjacent Skagit Valley Provincial Park or in several ecological reserves.

Acknowledgments

We thank Shane Ford for locating and examining the Shawnigan Lake population and Jenifer L. Penny for office assistance.

Conservation Evaluation of Slender Collomia, *Collomia tenella*, in Canada*

GEORGE W. DOUGLAS[1] and JENIFER L. PENNY[2]

[1] Deceased.
[2] Conservation Data Centre, British Columbia Ministry of Environment, Ecosystems Branch, PO Box 9993 Stn Prov Govt, Victoria, British Columbia V8W 9R7

Douglas, George W., and Jenifer L. Penny. 2006. Conservation evaluation of Slender Collomia, *Collomia tenella*, in Canada. Canadian Field-Naturalist 120(2): 175–178.

In Canada, Slender Collomia, *Collomia tenella*, is restricted to the Princeton area in southwestern British Columbia. The single population represents the northern limits of the species, which ranges from southwestern British Columbia, south in the western United States to Wyoming, Utah, Nevada and Oregon. In British Columbia, *C. tenella* is associated with an eroded section of a steeply sloping, southeast-facing sandy ridge. Population numbers fluctuate and in some years plants fail to appear. The major threats to *C. tenella* are through drilling for coalbed methane gas, sand removal for road construction, housing development and off-road recreational vehicles.

Key Words: Slender Collomia, *Collomia tenella*, endangered, distribution, population size, British Columbia

Slender Collomia, *Collomia tenella* A. Gray† (Polemoniaceae), is member of a genus of about 13 species found in North and South America (Hitchcock et al. 1959). Four species occur in British Columbia and Canada (Scoggan 1979; Pojar 1999). *Collomia tenella* was first recorded in Canada by Douglas et al. (1998a).

Collomia tenella is an ascending to spreading, freely branched, annual, tap-rooted herb up to 15 cm tall (Figure 1; Pojar 1999). The leaves are alternate, linear, entire, 1-5 cm long and 1.5 mm wide. Flowers are single or in pairs at the branch tips, in the leaf axils or at the forks of the branches. The pinkish to white corollas are five-lobed. The calyces, which bow out and often form purplish knobs at the sinuses, have 1-2 mm long, triangular teeth. The fruits consist of capsules with 1-seeded chambers; the seeds become sticky when moistened.

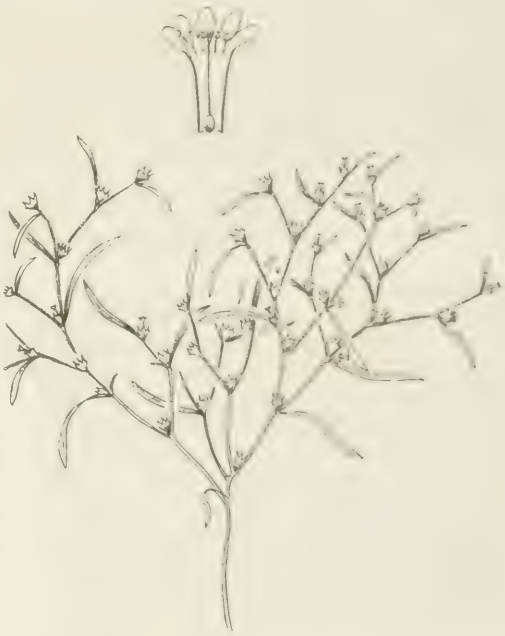

FIGURE 1. Illustration of *Collomia tenella* (line drawing from Douglas et al. 1999b).

North American and Provincial Ranges

Collomia tenella ranges from southwestern British Columbia, south in the western United States to Wyoming, Utah, Nevada and Oregon (Hitchcock et al. 1959). In Canada, *C. tenella* is known only from the Princeton area in British Columbia (Figure 2; Pojar 1999; Douglas 2002a).

Habitat

Collomia tenella occurs in the southwestern interior of British Columbia, along the Similkameen River valley in the Interior Douglas-fir biogeoclimatic zone (Hope et al. 1991). Climatic conditions in this region are continental, characterized by hot, dry summers, a fairly long growing season, and cool winters. A rain-

* The field work for the *Collomia tenella* project was funded by the British Columbia Conservation Data Centre. The results appear in the British Columbia Conservation Data Centre database and a rare plant manual (Douglas et al. 2002a). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Douglas and Penny 2003*) and the subsequent assessment of *Endangered* (COSEWIC 2003*). This paper includes more recent information that did not appear in the original status report.

† Taxonomy and nomenclature follow Douglas et al. (1998b, 1999a, 1999b, 2000, 2001).

shadow effect prevails in this area due to the presence of the Coast-Cascade Mountains to the west.

Within this region, *Collomia tenella* occurs on an eroded, steeply-sloped, southeast-facing section of a sandy ridge (Figure 3). The sandy ridge, formed by fluvial processes during recent glaciation, consists of fine-textured sands. The eroded sections of the slopes are sparsely vegetated with about 20% cover. The vegetation consists of a variety of herbs and shrubs including Arrow-leaved Balsamroot (*Balsamorhiza sagittata*), Timber Milk-vetch (*Astragalus miser*), Narrow-leaved Collomia (*Collomia linearis*), Thread-leaved Phacelia (*Phacelia linearis*), Silky Lupine (*Lupinus sericeus*), Saskatoon (*Amelanchier alnifolia*), Dalmation Toadflax (*Linaria genistifolia* ssp. *dalmatica*), Cheatgrass (*Bromus tectorum*), and Bluebunch Wheatgrass (*Pseudoroegneria spicata*). Scattered Douglas-fir (*Pseudotsuga menziesii*) and Ponderosa Pine (*Pinus ponderosa*) also occur on the ridge (Figure 3).

Biology

There is no information available on the biology and ecology of *Collomia tenella* in the literature. Since it is an annual plant it appears to be absent in some years if environmental conditions for seed germination and/or seedling survival are not favourable. Other annual members of the genus are self-compatible and self-pollinating (Wilken 1993). Seeds may be dispersed by animals since they are sticky when moistened.

Population Attributes

The single population of *Collomia tenella*, covering an area of less than 60 m^2, was discovered in 1997 in the Similkameen River valley, west of Princeton, British Columbia (Figure 2; Douglas et al. 1998a). Counts for the population in 1997, 2000, 2002, 2003 and 2004 were 10, 1, 0, 127 and 0, respectively. In 2003, the area occupied was ca. 56 square metres, with plants in four groups of 56, 67, 1 and 3 plants. These fluctuations indicate that seed germination and/or seedling success of this annual species is highly variable and thus, trends are difficult to determine. A fairly thorough search in adjacent areas in southern British Columbia have not revealed similar habitats or other populations of this species.

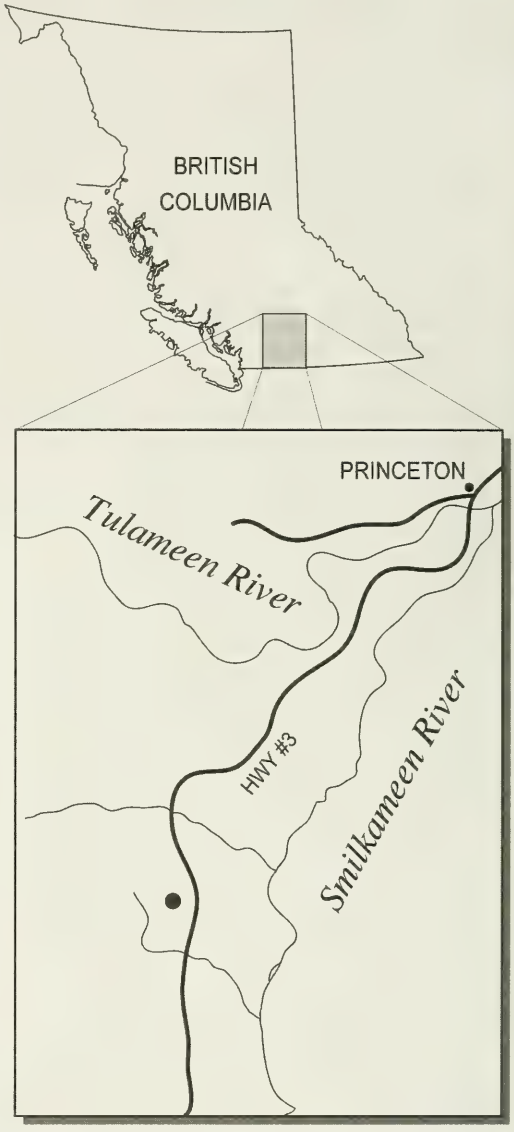

FIGURE 2. Distribution of *Collomia tenella* in British Columbia.

Provincial, National and Global Ranks

The British Columbia Conservation Data Centre has ranked *Collomia tenella* as S1 and placed it on the British Columbia Ministry of Environment Red list (Douglas et al. 2002a). This is the most critical category for imperilled rare native vascular plants in British Columbia. A rank of S1 is considered "critically imperilled because of extreme rarity (5 or fewer occurrences or very few remaining individuals) or because of some factors making it especially vulnerable to extirpation or extinction" (Douglas et al. 2002a). Since the species is restricted in Canada to British Columbia, the National rank is N1. Globally, *C. tenella* is ranked "G4?" or apparently secure but with a range of uncertainty which includes the possibility it is more vulnerable or conversely that is more widespread, abundant, and secure.

Threats and Protection

The major threats to *Collomia tenella* are through drilling for coalbed methane gas, sand removal for road construction, housing development and off-road recreational vehicles. In 2002, three test holes targeting coalbed methane gas deposits were drilled in the Simil-

FIGURE 3. *Collomia tenella* habitat occurs on the eroded section near the top of this sandy ridge south of Princeton, British Columbia. Prominent trees on the ridge are *Pseudotsuga menziesii* and *Pinus ponderosa*.

kameen area. If brought into production, the drilling, access roads and pumping stations could cause extensive degradation to the natural habitat in the area.

Other potential threats result from activities that are permitted in the Agriculture Land Reserve. The private property where *C. tenella* occurs is in the Agricultural Land Reserve, where primary land use is agriculture. For instance, some types of fill/soil removal are allowable without application to the Agricultural Land Commission (Provincial Agricultural Land Commission 2003*). On these lands, development pressures may not appear to be an issue at this time. The Agricultural Land Reserve status may prevent subdivision development, but does allow other activities that could also potentially threaten the populations. In recent years many tracts of Agricultural Land Reserve land in southern British Columbia has been converted to housing developments, shopping malls and golf courses, either by decisions of the Agricultural Land Commission or very rarely by an 'order in council' by the sitting provincial legislature.

Another threat likely to have a negative impact is recreational off-road vehicle use. The authors observed evidence of all-terrain vehicles and dirt bike use in the area of the sites in 2002. The steep and relatively unstable slopes where *C. tenella* occurs are highly susceptible to disturbance but at the same time, present a desirable challenge for off-roaders.

Although weeds are not a major threat to *C. tenella* populations, weed control activities do constitute a minor potential threat to populations. Under the *Weed Control Act*, an occupier must control noxious weeds growing or located on land and premises. Marginally specific chemical weed control compounds that kill broad-leaved plant species would likely also kill *C. tenella*. Noxious weeds such as Dalmation Toadflax (*Linaria genistifolia* var. *dalmatica*) and Cheatgrass (*Bromus tectorum*) occur in the *C. tenella* habitat and could increase. Currently the habitat is not highly invaded, but a variety of other introductions could also eventually take root there as they have in adjacent habitats in the surrounding landscape. Therefore, the ecological integrity of the *C. tenella* habitat could eventually become as comprised as some of these other surrounding habitats are.

An additional threat to the population of *C. tenella* is its vulnerability to extirpation due to the extremely small occupied area and population size. Such small populations are at risk of inbreeding depression (Primack 1998). Due to lack of genetic variation, these small populations are vulnerable to demographic and environmental variation. Furthermore, suitable habitats for *C. tenella* in the southern interior of British Columbia are extremely limited and thus, opportunities for colonisation are also limited.

Collomia tenella is on Schedule 1 of the federal *Species at Risk Act*. As part of its commitment to the National Accord (*National Accord for the Protection of Species at Risk*), the province is required to take measures to protect this species. A recovery strategy will be required under this commitment. Additionally, *C. tenella* is a potential candidate for listing under the provincial *Wildlife Amendment Act*.

Evaluation

The British Columbia Conservation Data Centre considers *Collomia tenella* to be Endangered in British Columbia (Douglas et al. 2002a) and the Committee on the Status of Endangered Wildlife in Canada has also assessed the species as Endangered (COSEWIC 2003*; Douglas 2005*). The single population is small and vulnerable to a number of threats. The small number of plants also reduces the potential for genetic variation which may be necessary to respond to environmental changes in the future. Without research on growth requirements and more demographic information, the stability of the present populations will remain unknown, but the population appears to be quite vulnerable.

Acknowledgments

We thank Frank Lomer for providing information on his original discovery of *Collomia tenella* in 1997 and for his help in finding the site in 2002. Thanks also to Shyanne J. Smith who assisted with fieldwork in 2004.

Conservation Evaluation of the Small-flowered Tonella, *Tonella tenella*, in Canada*

GEORGE W. DOUGLAS[1] AND JENIFER L. PENNY[2]

[1] Deceased.

[2] Conservation Data Centre, Ministry of Environment, Ecosystems Branch, P.O. BOX 9993 Stn Prov Govt, Victoria British Columbia V8W 9R7 Canada

Douglas, George W., and Jenifer L. Penny. 2006. Status of the Small-flowered Tonella, *Tonella tenella* (Scrophulariaceae) in Canada. Canadian Field-Naturalist 120(2): 179–182.

In Canada, the Small-flowered Tonella, *Tonella tenella*, is restricted to the west side of Saltspring Island in the Gulf Islands of southwestern British Columbia. This population represents the northern limits of the species which is disjunct from its main range in southern Washington (Columbia River gorge), through Oregon to central California. In British Columbia, *Tonella tenella* is associated with rock outcrops and dry, steep, sparsely forested talus slopes at elevations of 50 to 300 m. The population on Saltspring Island is on private property and not directly imperilled at this time. There is, however, a potential for housing development in the future on this waterfront site, thus the authors consider the species endangered.

Key Words: Small-flowered Tonella, *Tonella tenella*, endangered, distribution, population size, British Columbia.

The Small-flowered Tonella, *Tonella tenella* (Benth.) Heller†, is a member of a genus of only two species occurring in western North America (Hitchcock et al. 1959). It is the only species found in British Columbia and Canada (Pojar 2000). *Tonella tenella* was first recorded in Canada by Douglas and Ruyle-Douglas (1978).

Tonella tenella is a slender, ascending to prostrate, annual herb from a delicate taproot (Figure 1; Pojar 2000). The smooth, often branched stems are 5-25 cm long with opposite leaves 1-2 cm long. The leaves are stalked, simple, ovate to round, and few-toothed or lobed below and unstalked and deeply 2-3 lobed above. The blue or white flowers are small, slightly zygomorphic and long-stalked with deeply five-lobed calyces. The corollas are also five-lobed. There are four, epipetalous stamens and one pistil with 2 ovules. Anthers are 0.4 mm long. The fruits are obtuse to globe-shaped capsules containing 2 to 4, 1-1.5 cm long, wingless seeds.

Distribution

The southwestern British Columbia occurrence of *Tonella tenella* is disjunct from its main range in southern Washington (Columbia River gorge), through Oregon to central California (Wetherwax 1993; Pojar 2000). In Canada, *T. tenella* is known only from the west side of Saltspring Island in the Gulf Islands of southwestern British Columbia (Figure 2; Pojar 2000; Douglas et al. 2002a, 2002b).

FIGURE 1. Illustration of *Tonella tenella* (Line drawing from Douglas et al. 2000)

* The field work for *Tonella tenella* was funded by the British Columbia Conservation Data Centre. The results appear in the British Columbia Conservation Data Centre database and a rare plant manual (Douglas et al. 2002a). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Douglas and Penny 2003*) and the subsequent assessment of *Endangered* (COSEWIC 2003*). This paper includes more recent information that did not appear in the original status report.

† Taxonomy and nomenclature follows Douglas et al. (1998a, 1998b, 1999a, 1999b, 2000, 2001) and Schofield (1992).

TABLE 1. Locations and sizes of *Tonella tenella* subpopulations on Saltspring Island, British Columbia.

Collection site	Last Observation	Collector	Number of plants/area (m^2)
1- Upper slope, south	1976	Douglas	unknown
2- Upper slope, north	2002	Lomer	56+ /40.18
3- Mid-slope	2002	Lomer	100-150/15
4-Lower slope	2002	Douglas	65+/-15/6
5- ca. 10 m uphill from beach	2002	Lomer	30 /1

Habitat

Tonella tenella sites in British Columbia are found in a climatic and floristic anomaly in coastal British Columbia, the dry Coastal Douglas-fir (*Pseudotsuga menziesii*) Zone (Nuszdorfer et al. 1991) of southeastern Vancouver Island. This area is in a rainshadow belt created by the Olympic Mountains to the south, resulting in a relatively warm and dry Mediterranean climate.

Within this region, *Tonella tenella* occurs on west-facing slopes on stable talus. This talus occurs in open Big-leaf Maple (*Acer macrophyllum*)-Arbutus (*Arbutus menziesii)* forests, where associates include Cleavers (*Galium aparine*), Little Western Bitter-cress (*Cardamine oligosperma*), Miner's-lettuce (*Claytonia perfoliata*), Common Vetch (*Vicia sativa*), Barren Brome (*Bromus sterilis*), and Large-flowered Blue-eyed Mary (*Collinsia grandiflora*) or in open Douglas-fir – Arbutus – Garry Oak forests with Oregon Beaked Moss (*Kindbergia oregana*), heron's-bill moss (*Dicranum* species), Harford's Melic (*Melica harfordii*), *Galium aparine*, Upright Hedge-parsley (*Torilis japonica*) and Barren Brome (*Bromus sterilis*).

Biology

Species of *Tonella*, along with its sister genus, Blue-eyed Mary (*Collinsia*) of the tribe Collinsieae, are self-compatible annuals (Armbruster et al. 2002). *Tonella tenella* is considered a small-flowered type and according to Armbruster et al. (2002), large- and small-flowered taxa appear to have differences in timing of self-pollination. Large-flowered taxa maintain herkogamy (spatial separation of anthers and stigmas) early in anthesis by differential elongation of staminal filaments, while small-flowered taxa do not show this elongation pattern. As a result, large-flowered taxa experience a delay in self-pollination whereas in small-flowered taxa, anther-stigma contact and self-pollination occur early. Furthermore, the stigmas are receptive to pollen-tube growth early in *Tonella* species. Small-flowered populations are almost certainly autogamous (Armbruster et al. 2002). Low elevation pollinators for the tribe include the insects *Bombus, Anthophora, Emphoropsis, Synhalonia* and *Osmia* (Armbruster et al. 2002).

Population Attributes

Four small subpopulations of *Tonella tenella* were recently confirmed in 2002 at the Saltspring Island site. These subpopulations, plus an earlier (1976) collection record, occur in a narrow band extending up the mountainside for about 425 m. The subpopulations consisted of 6 to 356 plants with areas of 1 to about 40 m^2 (Table 1). Since the plant is inconspicuous and extremely difficult to detect, it is quite likely other subpopulations occur on the slope.

Provincial, National and Global Ranks

Globally, *Tonella tenella* has a rank of G5 indicating that in most of its range the plant is common. Since the species is restricted to British Columbia it has a national rank of N1. Provincially, *T. tenella* has been ranked as S1 by the Conservation Data Centre and appears on the British Columbia Ministry of Environment Red List (Douglas et al. 2002a). This is the most critical rank that can be applied to species at the provincial level and indicates that the species is "critically imperiled because of extreme rarity (typically five or fewer occurrences or very few remaining individuals) or because of some factor(s) making it especially vulnerable to extirpation or extinction".

Threats and Protection

The most immediate threat to *Tonella tenella* in British Columbia is habitat destruction through a housing development on waterfront private property. Suppression of both natural and human-induced fires in the last century may also have had an effect on the survival of *T. tenella*. The vegetation in this region would naturally be maintained by fires; however, in their absence, high fuel loads build and catastrophic fires could result. This may result in unsuitable conditions for *T. tenella*. Introduced species are also a problem. The vegetation characterizing the *T. tenella* site has been altered by the introduction of European species. Although a large number of native forbs occur in these areas, much of the vegetation is dominated to a large extent by introduced species, particularly grasses, including a number of species of *Bromus*. The *Tonella tenella* site occurs on private land.

Tonella tenella is not formally protected in British Columbia; however, it could be in the future since this species is a potential candidate for listing under the provincial *Wildlife Amendment Act* (2004). As part of its commitment to the National Accord (*National Accord for the Protection of Species at Risk*), the province is required to take measures to protect this species. It is on Schedule 1 of the federal *Species At Risk Act* and a recovery strategy will be required.

Evaluation of Status

The British Columbia Conservation Data Centre considers *T. tonella* to be Endangered in British Columbia (Douglas et al. 2002a). The Committee on the Status of Endangered Wildlife in Canada has also assigned this species to the Endangered category (COSEWIC 2003*). Only one extant population of *Tonella tenella* is known in British Columbia; thus, the loss of the one site would result in the loss of the species from British Columbia and Canada. Potential housing developments threaten *T. tenella* in Canada since the one site occurs on private oceanside property.

Acknowledgments

We thank Frank Lomer for his assistance with field work and Marilyn Lambert for providing water transportation.

Douglas, George W., Jenifer L. Penny, and Ksenia Barton. 2006. Conservation evaluation of Stoloniferous Pussytoes, *Antennaria flagellaris*, in Canada. Canadian Field-Naturalist 120(2): 183–187.

In Canada, Stoloniferous Pussytoes, *Antennaria flagellaris*, is restricted to the Similkameen River valley south of Princeton, in south-western British Columbia. The three populations represent the northern limits of the species which ranges from south-western British Columbia, south in the western United States to Idaho, Wyoming, Nevada and California. In British Columbia, *Antennaria flagellaris* is associated with eroded, unstable, calcareous clay seepage slopes on open, southerly aspects. This habitat is infrequent in the Similkameen River area and the few existing plant populations could easily be extirpated through slight changes in drainage through drilling for coalbed methane gas, road-building, or housing development.

Key Words: Stoloniferous Pussytoes, *Antennaria flagellaris*, endangered, distribution, population size, British Columbia.

Stoloniferous Pussytoes, *Antennaria flagellaris* (A. Gray) A. Gray† is a member of a genus of approximately 35 species mainly of North America but also found in South America (Cronquist 1994). Fifteen species occur in British Columbia (Douglas 1998) and approximately 18 in Canada (Kartesz 1999). *Antennaria flagellaris* was first recorded in Canada by Douglas et al. (1998a).

Antennaria flagellaris is a stoloniferous, short-lived perennial from a fibrous root (Figure 1; Douglas 1998). The stolons are up to 10 cm long while the few central flowering stems are up to 3.5 cm tall. The numerous basal leaves and the few stem leaves are linear to linear-oblanceolate, silky woolly-hairy and 1-3 cm long. The flower heads are terminal with involucres of two types. The female involucres are 7-13 mm tall bracts that are tinged brown or reddish-brown, thinly woolly-hairy below. The male involucres are 4-7 mm tall translucent bracts that are brownish at the tips. The female flowers are 5-7 mm tall while the male flowers are 3-4.5 mm tall. The single-seeded achenes are elliptic, warty and 2-3 mm long with a 6-8 mm tall pappus that has white, hairlike bristles.

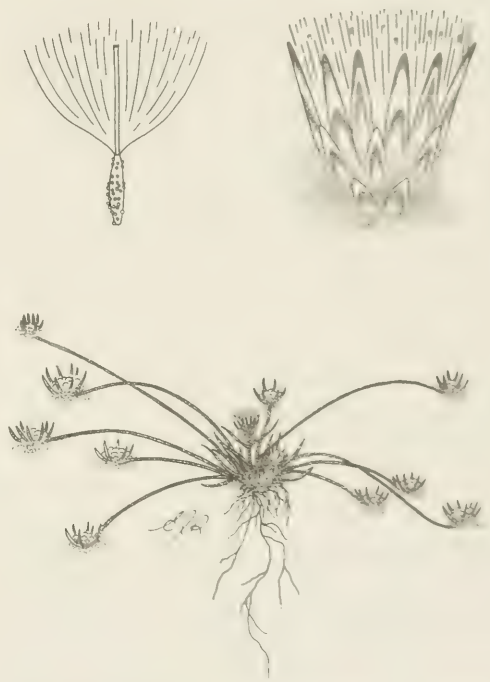

FIGURE 1. Illustration of *Antennaria flagellaris* (Line drawing by Elizabeth J. Steven in Douglas et al. 1998, 2002b).

Distribution

Antennaria flagellaris ranges from southwestern British Columbia, south in the western United States to Idaho, Wyoming, Nevada and California (Cronquist

* The field work for *Antennaria flagellaris* was funded by the British Columbia Conservation Data Centre. The results appear in the British Columbia Conservation Data Centre database and a rare plant manual (Douglas et al. 2002a). This information formed the basis for a Committee on the Status of Endangered Wildlife in Canada status report (Douglas and Penny 2004*) and the subsequent assessment of *Endangered* (COSEWIC 2004*). This paper includes more recent information that did not appear in the original status report.

† Taxonomy and nomenclature follow Douglas et al. (1998b, 1999, 2001).

TABLE 1. Locations and Population Sizes for *Antennaria flagellaris* near Princeton, British Columbia.

Collection site	Last Observation	Collector	Number of plants/area (m^2)
1. Stevenson Creek	1997	Lomer	50 ± 3 or 4
2. Whipsaw Creek, 2 km N of	1997	Lomer	Unknown

4. Tracey Lake	2003	Lomer	4-500/84

1994). In Canada, *A. flagellaris* is known only from along a 3.2-km length of Highway #3 in the Similkameen River valley south of Princeton in southwestern British Columbia (Figure 2; Douglas 1998; Douglas et al. 1998a, 2002a, b).

Habitat

Antennaria flagellaris occurs in the southern interior of British Columbia along the Similkameen River valley in the lower montane zone in the Interior Douglas-fir biogeoclimatic zone (Hope et al. 1991). Climatic conditions in this region are continental, characterized by hot, dry summers, a fairly long growing season, and cool winters. A rainshadow effect prevails in this area due to the presence of the Coast-Cascade Mountains to the west. Within this zone, *A. flagellaris* occurs in calcareous, gravelly-clay soils or gravelly sands. The sites are characterized by a unique hydrology. The slopes, which are moderate (20-30%) with open southerly aspects, are eroded, unstable, and characterized by ephemeral seepage. These moist microsites are saturated by underground water in the winter and dry up in the summer. The slow down-slope movement that occurs as a result of the unusual hydrology is unique in the region and excludes many taxa which are not able to tolerate the conditions. As a result, the slope is disturbed and sparsely vegetated with *A. flagellaris* being the dominant component (Figure 3).

Vegetation in the vicinity of the *A. flagellaris* sites is characterized by Big Sagebrush (*Artemisia tridentata*) shrub/grassland with scattered Ponderosa Pine (*Pinus ponderosa*) and Douglas-fir (*Pseudotsuga menziesii*) [Nomenclature follows Douglas et al. 1998b, 1998c, 1999 and 2001]. The sites occur at the western edge of the distribution of open shrub/grassland at that elevation. Associates of *A. flagellaris* include Cushion Buckwheat (*Eriogonum ovalifolium* var. *nivale*), Parsnip-flowered Buckwheat (*E. heracleoides* var. *angustifolium*), Swale Desert-parsley (*Lomatium ambiguum*), Thread-leaved Sandwort (*Arenaria capillaris* ssp. *americana*), Slender Wheatgrass (*Elymus trachycaulus*), One-spike Oatgrass (*Danthonia unispicata*), Common Rabbit-brush (*Ericameria nauseosus* var. *speciosa*), and Cut-leaved Daisy (*Erigeron compositus* var. *glabratus*). No non-native species were found in association with *Antennaria flagellaris*.

Biology

Little information is available on the biology of *A. flagellaris* in British Columbia. Only basic reproductive facts have been compiled about the species.

Antennaria flagellaris is a short-lived perennial, dioecious (male and female structures on separate plants) and wind-pollinated. This species produces seeds sexually by outcrossing (Bayer 1996). The fruits consist of single-seeded achenes. The numerous hair-like bristles of the mature achene facilitate its dispersal by wind.

Antennaria flagellaris also reproduces vegetatively by producing stolons that terminate in plantlets. Initially, the mother plant provides the plantlet with nutrients via the stolon. The genetically identical plantlets eventually become independent plants as stolons are severed. This mode of reproduction results in very restricted dispersal, as stolons only grow up to 10 cm long (Douglas 1998).

Population Attributes

There are three recently surveyed populations of *Antennaria flagellaris* in the Similkameen River valley, south of Princeton, British Columbia (Table 1). These populations occur along a 3.2-km length of Highway #3 (Figure 2). The populations range from a couple of square metres to over 2100 m^2 in size and number from 50 to approximately 1 400 000 ± 100 000 plants.

Short- and long-term trends for these populations are unknown but can be expected to vary markedly due to differences in yearly plantlet survival, seed germination and seedling success. Growing conditions on the ephemerally moist, clay slopes may vary from year to year according to normal climatic fluctuations affecting site hydrology.

Provincial, National and Global Ranks

Globally, *Antennaria flagellaris* has a rank of G5? indicating that in most of its range the plant is apparently secure to demonstrably widespread, abundant, and secure. Since the species is restricted to British Columbia it has a national rank in Canada of N1. Provincially, *Antennaria flagellaris* has been ranked as S1 by the Conservation Data Centre and appears on the British Columbia Ministry of Environment Red list (Douglas et al. 2002a). This is the most critical rank that can be applied to species at the provincial level and indicates that the species is "critically imperiled because of extreme rarity (typically five or fewer occurrences or very few remaining individuals) or because of some factor(s) making it especially vulnerable to extirpation or extinction".

Threats and Protection

The major threat to populations of *Antennaria flagellaris* are through drilling for coalbed methane gas,

road construction, housing developments and off-road recreational vehicles. In 2002 three test holes, targeting coalbed methane gas deposits, were drilled in the Similkameen valley. If brought into production the drilling, access roads and pumping stations could cause major degradation in the area.

The southern interior of British Columbia has recently seen an increase in housing projects and the Princeton area is no exception. Any developments which even slightly change groundwater levels could be devastating to this taxon. Furthermore, suitable habitats for *A. flagellaris* are extremely restricted in Canada, only occurring in the Princeton area, thus opportunities for colonisation are extremely limited.

Although weeds are not a major threat to *A. flagellaris* populations, weed control activities do constitute a minor potential threat to populations. Under the *Weed Control Act*, an occupier must control noxious weeds growing or located on land and premises; thus marginally specific chemical weed control compounds, that kill broad-leaved plant species, would likely be fatal to *A. flagellaris*.

Recreational off-road vehicle use could also present a threat due to the nature of the steep, clay slopes where *A. flagellaris* occurs. When moist, this habitat would be highly susceptible to disturbance and at the same time, be at its most desirable to off-road users. Overuse of the habitat in this way could disturb the sites enough to radically alter the hydrological regime, and promote the establishment of non-native species.

Other potential threats result from activities that are permitted in the Agriculture Land Reserve. The private property where *A. flagellaris* occurs is on the Agricultural Land Reserve, where primary land use is agriculture. For instance, some types of fill/soil removal are allowable without application to the Agricultural Land Commission (Provincial Agricultural Land Commission 2003*). On these lands, development pressures may not appear to be an issue at this time. The Agricultural Land Reserve status may prevent subdivision development, but does allow other activities that could also potentially threaten the populations. In recent years many tracts of Agricultural Land Reserve land in southern British Columbia have been converted to housing developments, shopping malls, and golf courses, either by decisions of the Agricultural Land Commission or, very rarely, by an "order in council" by the sitting provincial legislature.

An additional threat to the population of *A. flagellaris* is its vulnerability to extirpation due to the extremely small occupied area and population size. Such small populations are at risk of inbreeding depression (Primack 1998). Due to lack of genetic variation, these small populations are vulnerable to demographic and environmental variation. Furthermore, suitable habitats for *C. flagellaris* in the southern interior of British Columbia are extremely limited and thus opportunities for colonisation are also limited.

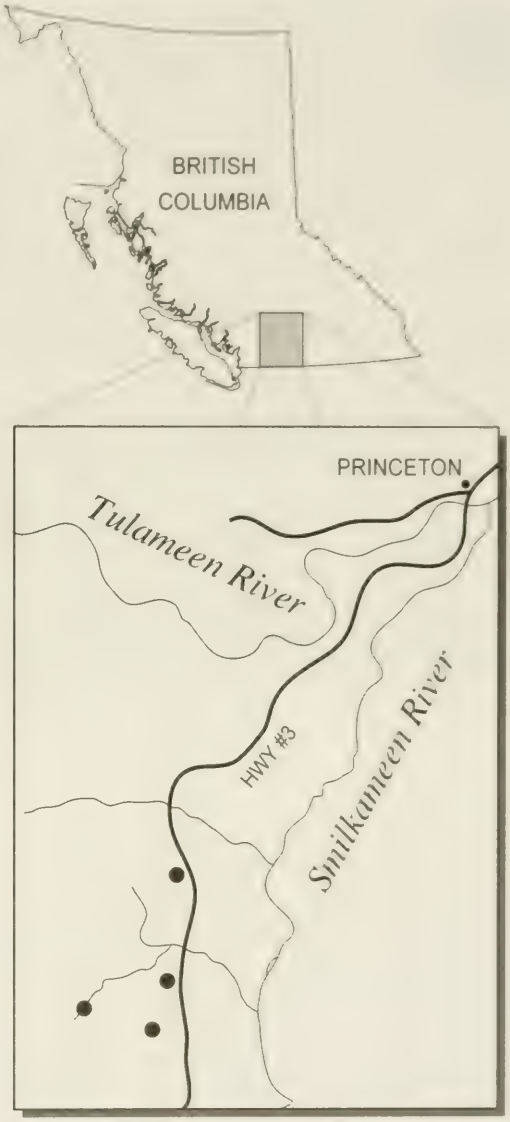

FIGURE 2. Distribution of *Antennaria flagellaris* in British Columbia.

Antennaria flagellaris is not formally protected in British Columbia, however, it could be in the future since this species is a potential candidate for listing under the provincial *Wildlife Amendment Act* (2004). As part of its commitment to the National Accord (*National Accord for the Protection of Species at Risk*), the province is required to take measures to protect this species. It is on Schedule 1 of the federal *Species At Risk Act* and a recovery strategy is expected to be completed by the summer of 2006.

FIGURE 3. Open habitat of *Antennaria flagellaris* in the Princeton area. *Antennaria flagellaris* is abundant in the open areas between clumps of *Eriogonum heracleoides* var. *angustifolium* and *Ericameria nauseosus* var. *speciosa*.

Evaluation

The British Columbia Conservation Data Centre considers *A. flagellaris* to be Endangered in British Columbia (Douglas et al. 2002a). The Committee on the Status of Endangered Wildlife in Canada has also assigned this species to the Endangered category (COSEWIC 2004*). The three populations are small and vulnerable to a number of threats. With limited knowledge of the plants, biological and ecological requirements, this species is vulnerable to extirpation in British Columbia. Without research on growth requirements and further demographic information, the stability of the present populations will remain unknown. The limited number of plants also reduces the potential for genetic variation which may be necessary to respond to environmental changes in the future.

Acknowledgments

We thank Frank Lomer for providing information on his original discovery of *A. flagellaris* and for his assistance in relocating the sites in 2002 and 2003.

[3]Corresponding author: e-mail: rick.rosatte@ontario.ca

Rosatte, Rick, and Joe Neuhold. 2006. Late-born Elk, *Cervus elaphus*, calf observed near Bancroft, Ontario. Canadian Field-Naturalist 120(2): 188–191.

A recently born male Elk (*Cervus elaphus*) calf was observed and photographed approximately 30 km east of Bancroft, Ontario, on 5 October 2004. Based on the gestation period for Elk, the estimated conception date was between late December 2003 and early January 2004. This is unusual as the majority of calves are born between late May and early June with conception having occurred in September/October. This reproductive strategy allows for an optimum growth period for calves to occur before the onset of winter which increases the probability of survival. An eleven-year-old cow Elk was identified as the mother of the late born calf. The age of the cow, and her inability to meet the annual energy requirements necessary for normal reproduction, may have contributed to the late conception and parturition dates.

Key Words: Elk, *Cervus elaphus,* Elk calf, restoration, late-born, Ontario.

In 1998, the Ontario Ministry of Natural Resources (OMNR) and partner organizations implemented a plan to restore Elk (*Cervus elaphus*) to Ontario, Canada (Bellhouse and Broadfoot 1996). Between 1998 and 2001, 443 elk acquired from Elk Island National Park (EINP), Alberta, were released in four different areas of Ontario; Lake of the Woods, Lake Huron/North Shore (near Blind River), French River/Burwash, and Bancroft/North Hastings (Rosatte et al. 2002). In total, 120 Elk were released during 2000/2001 in the Bancroft/North Hastings area at a location near Gin Lake (UTMC = 304000E 4990000N). Each summer, Elk calves have been observed and each winter, Elk calf surveys were conducted using OMNR helicopters to determine Elk calf survival and estimate the size of the herd.

On 5 October 2004, a male Elk calf with spots, estimated to be about three weeks of age, was observed and video taped near Hartsmere, Ontario (UTMC= 300000E 4995000N), approximately 25 km east of Bancroft, Ontario (Figure 1). The calf weighed about 25-30 kg based on body size; average birth weights for Elk calves are 15-22 kg (Hudson et al. 2002). On 1 November 2004, the calf was again observed nursing from a 11-year-old cow Elk which had been ear-tagged (All-Flex ear-tag # 347), weighed (238 kg), and radio-collared (Lotek GPS Collar- 148.115 Mhz) at EINP, Alberta, and released in the Bancroft/North Hastings, Ontario, area during April 2001. The calf was observed nursing from the cow during December 2004 and January 2005. The calf, still with spots, was photographed again on 1 February 2005, near Hartsmere, Ontario (Figure 2). It was with a group of 38 Elk comprised of 13 bulls {4 mature (>5yr), 4 yearlings, 5 immature (2-4 yrs), 8 calves, and 17 cows (which included the calf's mother – Figure 3)}. Based on observation during January/February 2005 the late-born calf with spots was estimated to be 25%-35% smaller than the other calves (Figure 2). Those calves were of a size comparable to Elk calves handled at EINP, Alberta, where calf weights averaged 120 kg (264 lb) (n=16) during January 2001. These weights are comparable to 8-9 mo old Elk calves in other studies that were born during early spring and summer (Cook 2002; Peek 2003). Unfortunately, the spotted calf was killed on 25 February 2005. Based on tracks in the fresh snow, injuries to the calf, and blood on the antlers of a mature bull Elk, the calf was likely gored to death.

Gestation periods for Elk range between 247-262 days with a mean of about 255 days (Bubenik 1982; Hudson et al. 2002). As this calf was first observed on 5 October 2004, conception must have occurred during late December 2003 or early January 2004. Wishart (1981) reported a cow Elk in Alberta that was shot in September 1979 and had a fully developed fetus. In this case, the conception date was estimated to be January 1979 and the cow was estimated to be 10 years of age. In Elk, reproductive success generally declines after 7 years of age (Raedeke et al. 2002).

One adaptive strategy of Elk is the production of highly developed, rapid growing, large young, so that calves quickly reach a size that maximizes survival during winter (Geist 2002). The high energy requirements for rapid growth of Elk calves is met through the energy acquired from maternal milk. Elk calves acquire most of their nutritional requirements during their first month of life from milk; however, after this neonatal period, requirements are greater and the ingestion of solid forage is required. That is why parturition throughout most of Elk range is early spring and summer (late May/early June) when forage is high in protein and nutritious (Hudson et al. 2002). The timing

FIGURE 1. Late born elk calf with spots photographed by J. Neuhold near Hartsmere, Ontario, on October 5, 2004.

of calving for Elk is such that inclement winter/spring weather is avoided but is early enough (e.g. June) so that calves can attain sufficient weight and size to survive the winter (Hudson et al. 2002). Juvenile Elk have evolved to reduce or cease growth during fall and winter, when the nutritive value of forage declines. Cook et al. (1996) reported that calf growth in mid-November was 50% of that found in September and hypothesized that the nutritional strategy of Elk calves during the late fall/early winter was primarily to maintain condition rather than maximizing growth. Inevitably, energy acquisition for rapid growth becomes a problem for late-born calves, as not only is forage less nutritious during the fall and winter, but milk production in lactating cow Elk also declines during that period due to poor quality forage (Cook et al. 1996; Cook 2002). In addition, survival was found to be lower for late-born Elk calves in Yellowstone National Park than for earlier-born calves (Singer et al. 1997), and calf mortality during winter was primarily due to malnutrition. The calf in this study was observed nursing in mid-January 2005 and supplemental feeding by people in the area may have provided sufficient energy for the cow to continue milk production during the winter period.

Nutrition and lactation can affect the timing of estrous in Elk and subsequently the parturition date (Cook 2002). Generally, cows that are suckling a calf during the rut come into estrous later than cows that do not have a calf (Hudson et al. 2002). During the early part of rut, estrous approximates 21 days but is variable (19-25 days) (Bubenik 1982) and estrous length increases and becomes irregular during the later stages of the breeding period (Hudson et al. 2002). Three to four estrous periods during one breeding season are possible with a refractory period of 62 days between sequential estrous cycles (Bubenik 1982) and Elk can be in heat as late as February. Older aged ungulates often cannot support production or reproduce (Cameron 1994; Cook 2002). Generally, reproductive success for elk 11 years of age is low (Raedeke et al. 2002). The age of the cow in this study, and her inability to meet the annual energy requirements necessary for normal reproduction, may have contributed to the late conception and parturition dates.

Anderson, Christine S., Douglas B. Meikle, Alan B. Cady, and Robert L. Schaefer. 2006. Annual variation in habitat use by White-footed Mice, *Peromyscus leucopus*: The effects of forest patch size, edge and surrounding vegetation type. Canadian Field-Naturalist 120(2): 192-198.

White-footed Mice (*Peromyscus leucopus)* were trapped for two years in the exterior matrix, edge, and interior forest habitat sections of six forests patches in a fragmented agricultural landscape. We used data on the capture locations of *P. leucopus* individuals from the two years, which differed in rainfall (i.e., summer of 2000 with 50% more rain than summer of 1999), to assess how patch size, edge habitat, and surrounding habitat type influence habitat use and movements in populations of this forest habitat generalist. We found that the proportion of individuals subsequently captured in the forest edge from the exterior was 16 times greater in the wet year than in the dry year and approximately twice as many *P. leucopus* were not subsequently recaptured from the exterior matrix in the dry year compared to the wet year. For each year, captures between habitats did not differ in relation to patch size, edge forest habitat, or exterior matrix type. These results illustrate the generalist habitat preferences of *P. leucopus,* but emphasize annual variation in their behavior and distribution.

Key Words: White-footed Mice, *Peromyscus leucopus*, forest patches, habitat preference, edge habitat, exterior matrix, Ohio, Indiana.

Human activities have led to a reduction and fragmentation of secondary-growth deciduous forests in North America, as well as changes in the quality of the remaining habitat (Yahner 1988; Fahrig 1997). The effects of fragmentation include those related to loss of connectivity among remnant patches, and increases in edge habitat, which both can cause local changes in abundance, distribution, and species' persistence (Andren 1994, 1997; Murcia 1995). In addition, the fragmentation of forested habitat results in the creation of forest patches that vary in size. Studies have shown that there are taxonomic differences in the relationship between animal population densities and patch area. Insects and birds generally show a positive relationship, likely due to an avoidance of edge habitat, which is greater in proportion in smaller patches (Connor et al. 2000). The majority of mammal species show fairly constant population densities with patch area, this follows the theory of island biogeography (Bowers and Matter 1997).

In contrast, investigators have found a consistent negative relationship between density of the White-footed Mouse (*Peromyscus leucopus* Rafinesque), a forest habitat generalist, and forest patch area (Nupp and Swihart 1996, 1998; Krohne and Hoch 1999; Mossman and Waser 2001; Schmid-Holmes and Drickamer 2001; Anderson et al. 2003; Anderson and Meikle 2006). Although resource availability may influence population dynamics of small mammals (e.g., Nupp and Swihart 1996), there are other factors that may be responsible for the negative density-area relationship. One possibility is that dispersal is inhibited from smaller forest patches due to lower habitat quality in the matrix than under continuous forest cover (Brown and Litvaitis 1995; Nupp and Swihart 1998; Krohne and Hoch 1999). We hypothesize in the current study that if inhibited dispersal results in the negative density-area relationship, then fewer *P. leucopus* should tend to move from the forest edge to the agricultural fields surrounding smaller compared to those surrounding larger forest patches.

In addition to patch area, another consequence of forest fragmentation is an increase in the proportion of edge habitat in the landscape since smaller forest patches have a greater edge: interior ratio than larger forest patches. Forest edges usually exhibit differences in microclimate, species composition, and vegetation structure compared to forest interiors (Harris 1988; Saunders et al. 1991). These difference may influence abundance and distribution of animal species. Studies have found that some forest animals may prefer forest edges while others may avoid those areas (Harris 1988; Saunders et al. 1991; Murcia 1995). However, there is debate as to whether *P. leucopus* prefers forest edge to forest interior habitat. Some investigators have reported greater densities of *Peromyscus* spp. near edges (Cummings and Vessey 1994; Boyne and Hobson 1998; Manson et al. 1999), possibly because

vegetation in edge habitat has been shown to be structurally more complex compared to interior habitat (Cummings and Vessey 1994; Anderson et al. 2003). In contrast, others have found fewer mice and lower maternal survival and litter success in edge habitats, presumably because parasitism, predation and interspecific competition can be higher along edges (Matter et al. 1996; Morris and Davidson 2000; Wolf and Batzli 2001, 2004). Since there is no evidence to date of higher rates of predation on mice in forest edges, then we predict that mice may prefer the high quality vegetation in forest edges such that there would be higher recapture rates in forest edges than in forest interiors.

Another consequence of forest fragmentation is that forest patches are surrounded by a matrix of agriculture or residential development that may inhibit the movement of organisms (Fitzgibbon 1997; Collinge 1996). Even though the agricultural matrix surrounding forest patches may be considered "hostile" habitat for some species (Collinge 1996), generalists such as *P. leucopus* (Gottschang 1981) may disperse relatively easily (Lackey 1978) through row crop fields (Mossman and Waser 2001). However, it is not well understood whether matrix types (e.g., corn or pasture) differentially affect capture rates of White-footed Mice in the exterior matrix. M'Closkey and Lajoie's (1975) work suggests that *P. leucopus* may prefer corn over pasture because mice were absent from grasslands. Even though grasses may provide cover for mice from aerial predators, Getz (1961) also noted that individual *Peromyscus* avoided grassy sites under forest canopy (also see M'Closkey and Lajoie 1975) likely because it rustles as the mouse moves (Barnum et al. 1992). If surrounding habitat type influences movements of mice throughout the landscape, we predict that they may stay in or move into the surrounding matrix habitat at greater rates when the matrix is comprised of corn rather than pasture.

The purpose of this study was to use data on the first two captures of *P. leucopus* individuals in different habitats (i.e., exterior matrix, forest edge, and forest interior habitat) in small and large forest patches for two summers to test the hypotheses related to patch size, edge habitat, and surrounding habitat type as described above. In addition, we compared captures among habitats between two summers differing in rainfall amounts (i.e., one dry year and one wet year) because temporal variation in precipitation regulates rodent population dynamics (Lewellen and Vessey 1998). Utilizing data on habitat use instead of overall abundance, we assumed that if mice tended to prefer one habitat over another, then, on average, they would move into (or stay in) the preferred habitats in relatively high proportions. Since much of the work on the effects of forest fragmentation has been focused on birds, this study contributes to our understanding of how human-dominated landscapes influence habitat use and movements of populations of small mammals.

Methods

Study Area

Peromyscus leucopus were trapped in both 1999 and 2000 in the same three "small" (~5-9 ha) and three "large" (~110-150 ha) forest patches in a row-crop agricultural landscape covering approximately 144 km^2 in SW Ohio and SE Indiana, USA (study area, 39°51'N, 84°74'W; Anderson and Meikle 2006; Table 1). We analyzed data from four transects of six Sherman™ live traps (7.5 × 7.5 × 25.5 cm) that were placed perpendicular to the center of one edge of each patch, with each transect beginning 20 m exterior to and extending 30 m into the patch (Figure 1). The transects and the traps in each transect were spaced 10 m apart, resulting in a 30 m by 50 m grid with a total of 24 traps at each forest patch. The eight traps in the agricultural field outside of each forest patch were considered "exterior" and the next eight traps were considered "edge". The eight traps inside the forest patch were considered "interior" traps. Based on our previous findings (Anderson et al. 2003) and corroborated by Burke and Nol (1998), the width of the edge habitat was defined based on typical edge floristic features. The surrounding habitat type in the exterior matrix was either pasture or corn fields (Table 1).

Data collection

Traps were set on 26 nights in each forest patch between June and September in 1999 and 2000 for a total of 7488 trap-nights. When a mouse was captured initially it was lightly anesthetized with halothane and a 12 mm AVID® microchip (PIT tag) was injected under the scruff of its neck. To distinguish between *P. leucopus* (primarily a woodland species) and *P. maniculatus* (primarily a grassland species), which are morphologically similar and overlap in the nonforested habitat within the study area, saliva samples were analyzed for the migration of the amylase enzyme with polyacrylamide gel electrophoresis (Aquadro and Patton 1980; Bruseo et al. 1999). We followed the protocol of Bruseo et al. (1999) with minor modifications.

Each patch was trapped for two consecutive nights every 5-7 d and we recorded the date, identification number and location of every individual at every trapping event. Based on trap location we determined which habitat (i.e., exterior, edge, or interior) each individual was located in for its first capture and then where it was subsequently captured for its second capture event. It is possible that the length of time between any two capture events for a particular individual could be 24 hours apart or more. A fourth category for the subsequent capture was "not subsequently recaptured", which was used if the individual was not recaptured again after tagging. Only the first two capture events for each individual were analyzed so that each individual was included only once in the analysis to avoid pseudoreplication. In order to verify whether a mouse moving into a particular habitat reflects fidelity to this

TABLE 1. Description of study sites and their location, size, and surrounding habitat type (i.e., exterior matrix habitat) in 1999 and 2000.

*This patch was not included for tests involving surrounding habitat type since it was the only patch with soybeans.

habitat shift, we also analyzed the data for the first year using all captures of all mice instead of the first two capture events only (i.e., 188 mice captured a total of 901 times) and found similar results (not presented), suggesting a permanence of habitat shifts. Although over winter survival was very low (i.e., four known individuals) between the two years of this study (Anderson 2004), we did not include those four individuals in the data set for the second year. Rainfall amounts from the Ohio Agricultural Research & Development Center (OARDC) weather station on Miami University's Oxford campus (http://jrscience.wcp.muohio.edu/van tagepro/latestweather.html) were totaled for each summer month (June – August) in 1999 and 2000. The OARDC is located within the center of the study area.

Statistical analyses

Data on the proportion of mice trapped for their second capture in the exterior, edge, or interior habitats, or not subsequently recaptured, based on the three initial capture habitats (i.e., exterior, edge, or interior) were compiled (see Table 2). The data set was analyzed with PROC CATMOD using chi-square tests to determine whether captures among habitats differed in relation to patch size, surrounding matrix type, and year (SAS 1999-2000). Subsets of the data were analyzed with PROC FREQ using either chi-square tests or Fisher's exact tests when sample size was small ($n < 50$ or cells with values < 5; SAS 1999-2000). Data from each year were analyzed separately (see Results; Table 2). In post hoc analyses, Fisher's exact tests and chi-square tests were used where appropriate (Moore and McCabe 1993) with a Bonferroni adjustment to the level of sig-

TABLE 2. The habitat where each *Peromyscus leucopus* was trapped for its second capture based on where it was first captured in 1999 and 2000. Values are pooled across patch sizes and number of individuals and row percentages are given in parentheses.

Habitat where first captured	Habitat where subsequently (i.e., second) trapped			
1999	Exterior	Edge	Interior	Not subsequently recaptured
Exterior	9 (28%)	1 (3%)	2 (6%)	20 (63%)
Edge	6 (14%)	19 (43%)	10 (23%)	9 (21%)
Interior	2 (4%)	8 (15%)	17 (31%)	27 (50%)
2000	Exterior	Edge	Interior	Not subsequently recaptured
Exterior	1 (8%)	6 (50%)	1 (8%)	4 (33%)
Edge	1 (3%)	18 (46%)	10 (26%)	10 (26%)
Interior	0 (0%)	7 (13%)	23 (41%)	26 (46%)

nificance at $\alpha = 0.05$ (Sokal and Rohlf 1981). An unpaired t-test was used to test for a difference in mean monthly rainfall in the summer (June – August) of 1999 compared to 2000 (Sokal and Rohlf 1981).

Results

Patch size did not influence captures of *P. leucopus* among habitats in either 1999 or 2000 (1999: $\chi^2_3 = 0.9$, $P = 0.8$; 2000: $\chi^2_3 = 4.7$, $P = 0.2$). Hence, there was no difference in captures of mice among different habitats (i.e., exterior matrix, edge, or interior habitats, or not subsequently recaptured) for those individuals that had been initially trapped in edge habitat in small compared to large patches in either year (1999: Fisher's exact test, $n = 44$, $P = 0.5$; 2000: Fisher's exact test, $n = 39$, $P = 0.7$). Data were pooled across patch sizes within each year for all other analyses (Table 2). The proportion of *P. leucopus* recaptured in edge habitat (i.e., both the first and second captures occurred in edge habitat) compared to the proportion recaptured in interior habitat did not differ in either year (1999: $\chi^2_1 = 1.4$, $P = 0.2$; 2000: $\chi^2_1 = 0.2$, $P = 0.6$), suggesting that mice did not show a preference for edge or interior forest habitat. Surrounding habitat type (i.e., corn or pasture) did not influence the proportion of mice subsequently captured across different habitats that had been first captured in the edge in either year (1999: Fisher's exact test, $n = 44$, $P = 0.5$; 2000: Fisher's exact test, $n = 33$, $P = 0.2$). Likewise, surrounding habitat type did not affect subsequent captures across habitats for mice that had been first captured in the exterior matrix habitat in either year (1999: Fisher's exact test, $n = 32$, $P = 0.3$; 2000: Fisher's exact test, $n = 10$, $P = 0.3$).

When captures between habitats in 1999 and 2000 were compared, *P. leucopus* first captured in the exterior were subsequently trapped in different proportions among habitats in 1999 compared to 2000 (Fisher's exact test, $n = 44$, $P = 0.002$); specifically, the proportion of individuals subsequently captured in the forest edge from the exterior was 16 times greater in 2000 (6/12 = 50%) than in 1999 (1/32 = 3%; Fisher's exact test, $n = 44$, $P = 0.0008$; Table 2, Figure 2a). Likewise, a greater proportion of mice stayed in the exterior matrix compared to moving into the forest (edge and interior combined) in 1999 (9/12) than in 2000 (1/7; Fisher's exact test, $n = 20$, $P = 0.02$). Approximately twice as many *P. leucopus* were not subsequently recaptured after their first capture in the exterior matrix in 1999 (20/32 = 63%) compared to 2000 (4/12 = 33%), although the test was not significant (Fisher's exact test, $n = 44$, $P = 0.1$; Figure 2b). Mean monthly rainfall amounts were over 50% higher in the summer (June-August) of 2000 (mean ± SE = 11. 8 ± 0.9 cm) compared to 1999 (5.3 ± 1.0 cm; $t_4 = 4.7$, $P = 0.009$).

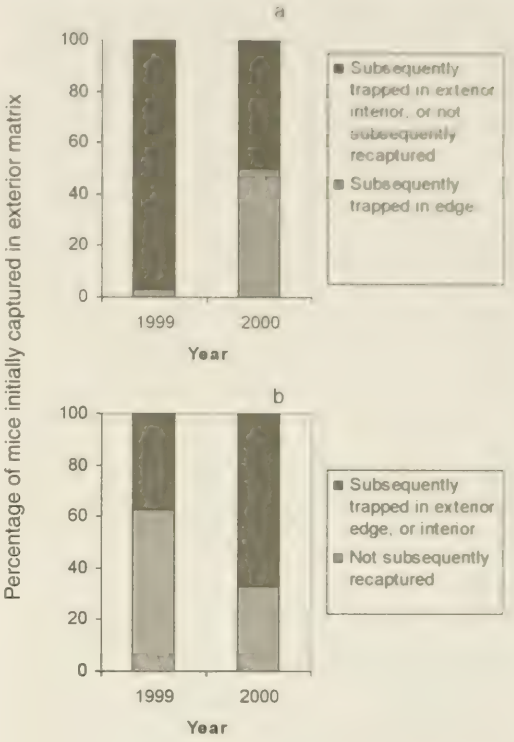

FIGURE 2. Percentage of mice (a) subsequently captured in forest edge habitat in 1999 compared to 2000 and (b) not subsequently recaptured in 1999 compared to 2000 (see Table 2 for sample sizes) that had been initially trapped in the exterior matrix habitat.

Discussion

Patch size

Studies have shown that populations of *P. leucopus*, unlike birds, insects, and most other mammals, have greater densities in smaller forest patches (Nupp and Swihart 1998; Krohne and Hoch 1999; Anderson et al. 2003). One proposed mechanism to account for this negative density-area relationship is that habitat quality is lower in the exterior matrix than in woodland sites (Nupp and Swihart 1996; Krohne and Hoch 1999). Predation pressure may be elevated in the agricultural fields surrounding smaller patches because some predators may attain higher densities in a landscape with a variety of land uses (Brown and Litvaitis 1995). We predicted that fewer mice would move from the forest edge to the agricultural fields surrounding smaller than larger forest patches, but our results did not support the inhibited dispersal hypothesis. Diaz et al. (1999) found no difference in movements of *Apodemus sylvaticus* to the exterior in relation to patch size, whereas Krohne and Hoch (1999) found that *P. leucopus* populations in Indiana had lower dispersal rates from smaller patches, a factor that may have resulted in higher densities in those patches (Adler and Levins 1994). Nupp and Swihart (1996) concluded that both reduced dispersal and greater abundances of food contributed to the high densities of *P. leucopus* they observed in small forest woodlots.

It is unclear why densities of *P. leucopus* tend to be higher in small forest patches (Anderson and Meikle 2006). One possibility is that immigration rates are in fact greater into smaller forest patches, resulting in higher densities in those patches (Bowman et al. 2002). However, we did not find that movements from exterior to the edge or interior habitats were greater in smaller than larger patches in this study. If smaller and larger forest patches do not vary in emigration and immigration rates, as our data suggest, then a second possibility is that other factors, such as greater food abundance or cover from predators, may have resulted in greater abundances of mice in smaller patches or in particular the edges of small patches (Nupp and Swihart 1996; Diaz et al. 1999; Anderson et al. 2003; Anderson and Meikle 2006). A third possibility is that lower densities in larger patches may be the result of mice dispersing to low density regions within the heterogeneous forest patch to alleviate high densities, with fewer sites likely present in smaller forest patches (Krohne and Burgin 1990; Krohne and Hoch 1999).

Edge habitat

Differences in species composition and vegetation structure in forest edges compared to forest interiors, regardless of patch size; may influence the distribution of small mammals within forest fragments (Matlack 1994; Collinge 1996). Currently, there are conflicting reports about the effects of edge habitat on the abundance and distribution of White-footed Mice (e.g., Cummings and Vessey 1994; Anderson et al. 2003; Wolf and Batzli 2004). We found that *P. leucopus* were recaptured in the same proportion in forest edge compared to forest interior habitat in either year. Our data on initial and second capture habitat locations support those studies that reported no difference in the relative abundance of mice in those two habitats (Heske 1995; Nupp and Swihart 1996, 1998). This result is somewhat surprising since forest edge habitats have been shown to have greater structural complexity in the understory vegetation compared to edge habitat (Anderson et al. 2003) and White-footed Mice have been shown to prefer areas with more plant cover (Drickamer 1990). One explanation could be that mice are not moving into edge habitat but are already present in high abundances with small territory sizes. Perhaps once territories are established in early spring, when movements among high (i.e., edge) and low quality (i.e., interior) habitats are negligible due to competitive exclusion.

Surrounding habitat type

Types of vegetation in the surrounding matrix habitat may differentially affect the population dynamics of rodent species in a fragmented landscape. For example, Wolf and Batzli (2004) found that predation risk for *P. leucopus* was higher at edges adjacent to restored prairies than at edges adjacent to agricultural fields. Our findings showed that *P. leucopus* moved in similar proportions from the forest edge into two different matrix habitat types (i.e., corn and pasture). This is in contrast to studies that have found that *P. leucopus* tend to avoid grassy habitats and can be found in corn fields at densities as high as those in woodlots (Getz 1961; M'Closkey and Lajoie 1975; Wegner and Merriam 1979, 1990). Mice in our study sites may have simply responded to the seasonal presence of cover and not to the type of cover (Cummings and Vessey 1994). Henein et al. (1998) designed a simulation model illustrating flexible and opportunistic responses of *P. leucopus* to landscape structure and connectivity via an expansion of their use of corn and small grain fields. Similar results have been found for *A. sylvaticus*, a mouse species also described as a habitat generalist (Garcia et al. 1998; Kozakiewicz et al. 1999).

Annual variation

Rainfall may impact rodent populations directly by influencing their reproductive status and survival, or indirectly in relation to changes in food sources and vegetative cover from predators (Kaufman et al. 1995; Kesner and Linzey 1997). Monthly rainfall data showed that totals in the summer of 2000 were almost 50% greater than in 1999. For mice initially captured in the exterior matrix habitat, we found that a greater proportion moved to the edge habitat and more were subsequently recaptured in the exterior matrix in the wet year compared to the dry year. If rainfall influenced patterns of capture among habitats, one explanation is that in 1999 (i.e., the dry summer) a higher proportion of mice were not subsequently recaptured from the exterior matrix habitat because they died due to poor conditions, or moved throughout the landscape in search of other better quality habitats (Kesner and Linzey 1997; Lidicker and Stenseth 1992). In 2000, the shrub and herbaceous layers in the forest habitat may have had more or higher-quality food sources compared to the exterior matrix as a consequence of rainfall which caused an influx of mice to the forest habitat (Parmenter and MacMahon 1983; Bowers and Dooley 1999; Hutchinson et al. 1999). Our results illustrate the generalist habitat preferences of *P. leucopus* but emphasize annual variation in their distribution within the forest and surrounding habitats. However, year-to-year differences in patterns of habitat use may be influenced by a number of variables, and a longer-term study would help to elucidate those factors (Kesner and Linzey 1997).

Acknowledgments

We thank the landowners for permission to use study sites, in addition to the Ohio Department of Natural Resources, Hueston Woods State Park, Miami University's Natural Areas Committee and Miami University's Ecology Research Center. We thank J. Bruseo, M. Spritzer, S. Vessey, and three anonymous reviewers for their valuable advice. K. Fielitz, J. Gliha, C. Harrison, R. Lim, A. Lohrey, D. Markert, M. Tarbox, K. Wolfe and especially R. Young provided valuable support in the laboratory and in the field. This work was

supported with funding from Sigma Xi and the Department of Zoology at Miami University. Research on live animals was performed in a humane manner and was approved by the Institutional Animal Care and Use Committee (IACUC) at Miami University (protocols #430 and #467).

Response of the Sea Louse *Lepeophtheirus salmonis* Infestation Levels on Juvenile Wild Pink, *Oncorhynchus gorbuscha*, and Chum, *O. keta*, Salmon to Arrival of Parasitized Wild Adult Pink Salmon

ALEXANDRA MORTON[1] and ROB WILLIAMS[2]

Morton, Alexandra, and Rob Williams. 2006. Response of the sea louse *Lepeophtheirus salmonis* infestation levels on juvenile wild Pink, *Oncorhynchus gorbuscha*, and Chum, *O. keta*, salmon to arrival of parasitized wild adult Pink Salmon. Canadian Field-Naturalist 120(2): 199-204.

Recent recurring infestations of Sea Lice, *Lepeophtheirus salmonis*, on juvenile Pacific salmon (*Oncorhynchus* spp.) and subsequent annual declines of these stocks have made it imperative to identify the source of Sea Lice. While several studies now identify farm salmon populations as sources of Sea Louse larvae, it is unclear to what extent wild salmonid hosts also contribute Sea Lice. We measured Sea Louse numbers on adult Pink Salmon (*Oncorhynchus gorbuscha*) migrating inshore. We also measured Sea Louse numbers on wild juvenile Pink and Chum salmon (*Oncorhynchus keta*) migrating to sea before the adults returned, and as the two age cohorts mingled. Adult Pink Salmon carried an average of 9.89 (SE 0.90) gravid lice per fish, and thus were capable of infecting the adjacent juveniles. Salinity and temperature remained favourable to Sea Louse reproduction throughout the study. However, all accepted measures of Sea Louse infestation failed to show significant increase on the juvenile salmon, either in overall abundance of Sea Lice or of the initial infective-stage juvenile lice, while the adult wild salmon were present in the study area. This study suggests that even during periods of peak interaction, wild adult salmon are not the primary source of the recent and unprecedented infestations of Sea Lice on juvenile Pacific Pink and Chum salmon in the inshore waters of British Columbia.

Key Words: Sea Lice, *Lepeophtheirus salmonis* Pink Salmon, *Oncorhynchus gorbuscha* Chum Salmon, *O. keta*, salmon farm, British Columbia

The sea louse *Lepeophtheirus salmonis* is a common salmon-specific parasite (Nagasawa et al. 1993; Kabata 1973). While their preferred Pacific host is the Pink Salmon (*Oncorhynchus gorbuscha*) (Nagasawa 1987; Nagasawa et al. 1993), *L. salmonis* is found on all species of Pacific salmonids, as well as Atlantic Salmon (*Salmo salar*), Sea Trout (*Salmo trutta trutta*), Rainbow Trout (*Salmo gairdneri*) and Artic Charr (*Salvelinus alpinus*). Once considered benign (Boxshall 1974; Nagasawa 1987; Berland 1993), *L. salmonis* is now a significant problem species on farmed salmon (Pike and Wadsworth 1999; Johnson et al. 2004). Salmon farms are a series of floating net pens attached to the shoreline or anchored in the nearshore. Salmon arrive from hatcheries and are fed in these pens for 18-24 months, then harvested and sold as food. All farm salmon in our study area were Atlantic Salmon.

Optimal salinity for *L. salmonis* survivorship and reproduction is 30‰ (Johnson and Albright 1991b), with copepodids tolerating salinities as low as 15‰ (Pike and Wadsworth 1999). *L. salmonis* hatch into a free-swimming naupliar stage directly from egg strings attached to the female's body (Johnson and Albright 1991a). The interval from hatching to infective capability (copepodid stage) is approximately 4 d at 10°C and 2 d at 15°C (Johnson and Albright 1991b). The copepodid stage is the first attached stage, thus abundant presence of this stage signals a local source of gravid Sea Lice and a host salmonid population. When wild salmon enter freshwater to spawn, the attached *L. salmonis* experience decay of life-processes leading to death (Hahnenkamp and Fyhn 1985; McLean et al. 1990; Johnson and Albright 1991b). As one would expect from an obligate parasite, there have been no reports of *L. salmonis* over-wintering off-host in the nearshore marine environment.

While early studies on juvenile wild Atlantic salmonids *Salmo salar* and *Salmo trutta* make no mention of parasitism by *L. salmonis* (Heuch and Mo 2001); Sea Lice are now reported in high numbers on wild European salmonids adjacent to farms (Tully et al. 1993; Birkeland 1996). Historically, researchers did not look specifically for *L. salmonis* on juvenile Pacific salmon in the inshore environment. However, the seminal works on juvenile Pink and Chum salmon (Healey 1978, 1982; Parker 1965; Parker and Vanstone 1966) did note the presence of the smaller sea louse, *Caligus clemensi* (Parker and Margolis 1964). *C. clemensi* is a generalist non salmon-specific parasite that has been reported on 13 species of fish (Jones and Nemec 2004*). It seems reasonable that if *Caligus* was noted, then the larger, more conspicuous *L. salmonis* would also have been reported had it been historically present on juvenile Pink salmon.

Today, Sea Lice are reported on juvenile Pink and Chum salmon in some areas of coastal British Colum-

bia and appear associated with salmon farming (Morton and Williams 2003; Morton et al. 2004; Morton et al. 2005; Krkosek et al. 2005; Krkosek et al. 2006). The impact of Sea Lice is host-size dependant (Grimnes and Jakobsen 1996; Bjørn and Finstad 1997) and this is critical to Pink and Chum salmon as they enter the marine environment at the smallest size of any salmonid. Pink and Chum Salmon weigh less than one gram in the study area (Broughton Archipelago) throughout March and April (Morton et al. 2005), and are without protective scales (A.M. personal observations). Juvenile Pink and Chum salmon exhibit prolonged inshore residency from March to September (Healey 1978). If some adult wild salmonids occur inshore year round, their numbers are low. The largest wild host population for *L. salmonis* are the mature Pink Salmon that enter coastal waters in July and run through September (Heard 1991).

Thus, in a natural setting, a system has evolved that isolates returning adult salmon from the most juvenile stage conspecifics. Juvenile Pink and Chum salmon do not share habitat with a significant *L. salmonis* host population until July, by which time they have grown to weigh several grams. Krkosek et al. (2005) report that after initial infection by salmon farms, juvenile salmon schools will re-infect themselves some weeks later as lice mature and being reproducing.

Salmon farming has altered this arrangement by siting 26 salmon farms in the nearshore environment of the Broughton Archipelago (Figure 1), each site holding potentially 1 million Atlantic Salmon (Naylor et al. 2003), a known host for *L. salmonis*. In July of 2003 there were approximately 6 million Atlantic Salmon among the 17 farm sites leased by Stolt Sea Farms with another nine sites leased by another company (Heritage) that did not report numbers (Orr *in press*). Orr (*in press*) reports an average of 2.2 – 9.2 gravid Sea Lice per salmon on the 6 million farm Atlantic Salmon for 2003-2004.

While salmon farms are now a recognized source of Sea Lice, this study further illuminates this subject by measuring the response in Sea Louse numbers on wild juvenile salmon to the arrival of a large population of this Sea Louse's preferred host, the adult Pink Salmon. We hypothesise that if wild adult salmon were a substantial source of Sea Lice on juvenile salmon in the study area, then the number of copepodid *L. salmonis* should rise in response to the arrival of in-migrating adult Pink Salmon. To test this, we first measured lice levels on juvenile Pink Salmon, then looked for evidence of copepodid Sea Louse recruitment subsequent to wild adult Pink Salmon arrival in the area.

Understanding the mechanisms of *L. salmonis* infestation of inshore juvenile wild salmon and the relative importance of both wild and farm lice sources has become crucial to both wild and farm salmon management. This study provides analysis on a previously unreported aspect of the dynamic between adult and juvenile Pacific salmon and Sea Lice.

Methods

This study took place in the 400 km^2 Broughton Archipelago in British Columbia. There are seven major Pink Salmon rivers and 26 Atlantic Salmon farm sites between the rivers and the open waters of Queen Charlotte Strait (Figure 1). The Broughton Archipelago's 200 km of inlets and 90 km of passages and small bays makes it ideal marine rearing habitat for juvenile Pink and Chum salmon (Healey 1978). Within this region, Fife Sound (Figure 1) through Tribune Channel is considered a primary route used by returning adult Pink Salmon (G. Neidrauer, Fisheries and Oceans Canada, Fisheries Patrolman, General Delivery, Simoom Sound, BC V0P 1S0 personal communication).

Juvenile Pink and Chum salmon were sampled once each week at the same sampling location from 1 June 2003 through 19 September 2003 (Figure 1). The salmon farm at this site was fallow, and without any farm salmon. A 50' × 4' beach seine of ⅛" mesh was used in June and a 120' × 8' beach seine with ¼" mesh and a ⅛" bunt was used for the remainder of the study. Sample size ranged from 20 to 30 fish per week. The juvenile salmon were placed individually in Whirlpak™ bags immediately after capture, laid on ice and then frozen. They were later examined under 30× magnification and the number of Sea Lice, their age-class and sex were determined and recorded using published taxonomic keys (Johnson and Albright 1991a). Adult female lice were classified as either virgin or gravid as per the Norwegian method of counting sea lice (Karin Boxaspen, Researcher, Institute of Marine Research, Bergen, Norway). Results are reported only for the salmon-specific Sea Louse, *L. salmonis*.

We used three independent methods to estimate the timing of the wild adult Pink Salmon return to the study area. First, we used measured Pink Salmon catch-per-unit directly at our juvenile salmon sampling site. We used two fishing rods with lures known to attract Pink Salmon in this area (A.M. personal observations). We fished for 166 hook-hours between 4 June and 19 September.

The second method compared our catch-per-unit-effort analysis with the timing of the adult return reported by Fisheries and Oceans Canada (DFO) as determined by their enumeration program on the known Pink Salmon-bearing streams nearby (Figure 1). The Fisheries and Oceans Pink Salmon enumeration flights began in the second week of August and continued through the end of October. Finally, a tourism operator in the Glendale River watershed (Figure 1) had guides on the river for 3 days in May, 11 days in June, 23 days in July, 28 days in August, and reported to us when Pink Salmon were first sighted.

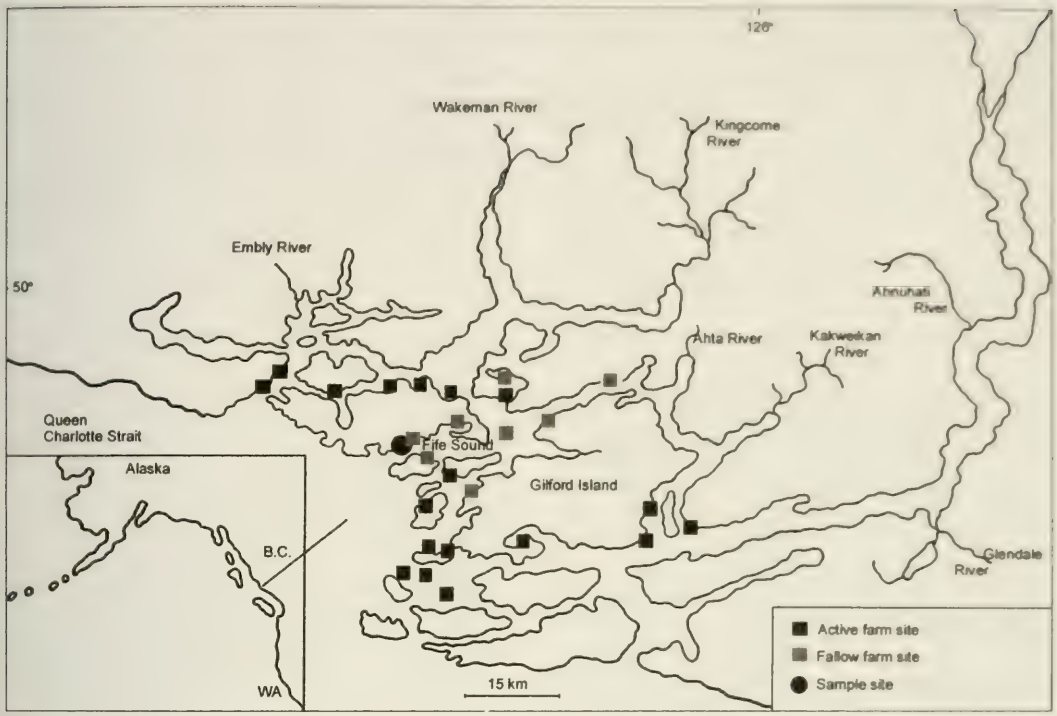

FIGURE 1. Study area, the Broughton Archipelago, showing major Pink Salmon rivers, salmon farm sites and status, and study site.

The adult salmon caught in this study were lifted from the water without a net and kept free from contact with any surface in order to reduce loss of lice. They were examined immediately for Sea Louse counts, stages and species identification using a hand lens. We estimated the infective capability of the returning adult salmon by counting gravid female sea lice per fish: a standard measure used to trigger de-lousing treatment of farm salmon to reduce infective capability and lower sea lice numbers on adjacent juvenile wild salmon (Heuch and Mo 2001).

Louse counts were not expected to follow a normal distribution. Rather than transforming the data, we made comparisons using Mann-Whitney U tests (MWU; the non-parametric equivalent of a two-sample t-test) in GraphPad version 3.05 by InStat (GraphPad Software Inc., 5575 Oberlin Drive, #110, San Diego, California 92121 USA).

We used the following standard measures of louse infestation rates (Margolis et al. 1982): prevalence = the proportion of fish infested with lice; intensity = the mean number of lice on each infected fish; and abundance = the mean number of lice on the entire sample.

Results

We fished for 47 "hook-hours" 4 June through July, without catching one adult Pink Salmon. We fished for 119 hook-hours in August until 19 September, and beginning on 4 August, caught 50 adult Pink Salmon at an average of 0.78 Pink Salmon/hook-hour (SE = 0.10, n = 17 fishing sessions, range 0-1.4 Pink Salmon/ hook-hour). Given that there was no variance in the 12 June/July fishing sessions (all 12 failed sessions to catch a fish), a Wilcoxon signed-rank test was conducted to assess whether the median catch-per-unit-effort in August and September differed significantly from the observed zero catch-per-unit-effort in June and July. The sum of positive ranks was 136, indicating that the median value was significantly greater than 0 ($P < 0.0001$).

Fisheries and Oceans Canada estimated that 188 730 Pink Salmon entered the Broughton Archipelago rivers from mid-August through September 2003 (G. McEachen, Fisheries and Oceans Canada, chief of conservation management for the central coast, Central Coast Area Office, 315-940 Alder Street, Campbell River, British Columbia V9W 2P8, personal commu-

TABLE 1. Mass, length, and sea lice infection of Pink and Chum salmon collected during the two sampling periods with average sea surface temperature and salinity for both time periods. "Total" signifies all *L. salmonis* and "cope" signifies copepodite *L. salmonis* only.

Period	n	Grams (SE)	Size cm (SE)	Salt % (SE)	Temp °C (SE)	Prevalence %		Abundance (SE) Range		Intensity (SE)	
						Total	Cope	Total	Cope	Total	Cope
June – July	623	6.94 (0.15)	8.47 (0.03)	29.1 (0.03)	12.1 (0.01)	43.0	7.2	1.20 (0.12) 0-42	0.079 (0.012) 0-2	2.79 (0.26)	1.09 (0.018)
August – 19 September	145	21.16 (0.57)	12.38 (0.10)	30.8 (0.11)	11.1 (0.05)	40.0	4.8	1.00 (0.25) 0-33	0.048 (0.018) 0-1	2.50 (0.58)	1 (0)

nication). This would indicate that Pink Salmon were present seaward of the rivers and within the study area for 2-3 weeks prior to the end of the second week of August, when they were first identified in the rivers, through September. We cannot be certain how many of these fish passed the sampling site, but Fife Sound is considered the primary migration corridor for adult Pink Salmon (Neidrauer, personal communication).

The tour operator and his guides looked for Pink Salmon on each of their tours, but did not see Pink Salmon in the largest Pink Salmon river in the study area, the Glendale River, until 20 August (H. Pattinson, owner/operator, Tide Rip Tours, 1660 Robb Avenue, Comox, British Columbia V9M 2W7 Canada, personal communication). Again, assuming that adults took two to three weeks to migrate through the Broughton Archipelago to reach the Glendale watershed, one would expect that the adults reached our sampling location in early August. In fact, these three methods show very good agreement, and all point to a best estimate return date for large numbers of wild adult Pink Salmon in the first days of August. Consequently, we estimate that juvenile Pink and Chum salmon were introduced to louse-infected adults around the first day of August.

We divided the pre- and post-exposure stages into two sampling periods: 1 June to 31 July, and 1 August to 19 September. As one would expect from a rapidly growing cohort, the juvenile salmon increased in both length and weight throughout the study (Table 1). The average seawater temperature and salinity varied slightly between the two sampling periods, but remained at all times within optimal range for *L. salmonis* (Table 1). The mean number of gravid lice on returning adult Pink Salmon was 9.31 (SE 0.93).

No measure of total Sea Louse occurrence varied between the sampling periods (Table 1) (abundance – MWU statistic: 43186, P = 0.4088; intensity – MWU statistic: 7153.5, P = 0.3412). As well, no measure of copepodite Sea Lice varied significantly (abundance – MWU 44072; P = 0.6448).

Given that there was no variance in the observed intensity of copepodid infection on juvenile salmon in the later sampling period (that is, all seven fish infected with copepodites carried a single copepodid louse), a Wilcoxon signed-rank test was used to assess whether the median early-season intensity differed from the observed intensity of 1 louse/fish in the later sampling season. The mean intensity of infection on the 45 fish infected with copepodites in the earlier sampling season was 1.09 (SE 0.043, median 1.00, range 1-2). This was not significantly greater than the 1 louse/infected fish observed in the later sampling season (sum of all signed ranks = 10, after correcting for ties; $P = 0.13$).

Discussion

The number of returning adult Pink Salmon carrying gravid Sea Lice was on the order of two hundred thousand, with approximately nine gravid Sea Lice per fish and thus we estimate that the juvenile Pink and Chum salmon in Fife Sound were exposed to the infective capability of close to two million gravid female Sea Lice. However no marked increase above the pre-existing background infection levels could be detected on juvenile salmon after the adult fish arrived in the area.

Even if the total number of Sea Lice failed to increase on juvenile salmon after the return of adult Pink Salmon, an increase in the proportion of lice at the copepodid stage would have indicated arrival of a source of Sea Lice that exceeded ambient levels. However, no increased copepodid settlement was observed. In fact, prevalence of copepodids was slightly lower after the adult Pink Salmon returned, which is as one would expect from an epizootic living out the course of its infestation. In the early, i.e., pre-exposure sampling period, 7.2% of juveniles sampled carried at least one copepodid, and after the adult Pink Salmon returned, 4.8% of juveniles sampled carried at least one copepodid. The juvenile salmon were traveling west out of an area where gravid Sea Lice occurred on farm salmon.

The decline we recorded in copepodite Sea Lice is contrary to what Krkosek et al. (2005) found where infected juvenile salmon re-infected each other as their farm-origin Sea Lice matured. The difference in

findings might be a result of geography. Krkosek et al. (2005) was conducted within the confined waterway of Tribune Channel, whereas this work occurred in an area of much greater flush at the archipelago edge. There are no juvenile Pink and Chum salmon in Tribune Channel in August. The juvenile Pacific salmon out-migrations and adult salmon in-migrations are generally timed such that interaction between the two cohorts occurs in open waters.

Ocean temperature and salinity were unlikely to have hindered parasite growth or transfer during August and September. Mean sea-surface temperature fell 1°C during the adult spawning in-migration, which had the potential to slow reproduction, but salinity increased, which favoured reproduction. Both values, however, were well within optimal range necessary for Sea Lice reproduction (Johnson and Albright 1991b; Boxaspen and Naess 2000; Tucker et al. 2000). Consequently, we conclude that the juvenile hosts in our study simply failed to respond measurably to exposure to a large influx of infested wild adult salmon.

We fully expected louse loads to increase when the adult Pink Salmon returned. We know that Sea Lice must be transmitted among wild salmon. The fact that Louse numbers did not increase in our study was surprising, and leads us to conclude that, compared to ambient levels of farm-origin parasitism in the Broughton Archipelago, the contribution of wild-source lice was negligible. We suspect the higher numbers of salmon-specific Sea Lice on juvenile Pink and Chum salmon in June and July originated from the population of several million, farmed Atlantic Salmon in the Broughton Archipelago in high-density open-net pens. Orr (*in press*) reports an average of several gravid sea lice per each of 6 million farm salmon during our study period, which translates into a very large number of copepodite sea lice occurring to the east of our study site area, but not at our study site itself which was adjacent to an empty salmon farm.

Why we did *not* find an increase in Sea Lice in August and September is perplexing. The mandatory 2-4 day dispersal term in the plankton layer likely limits Sea Louse recruitment rates to allow both parasite and host to thrive. Perhaps there were not enough wild adult Pink Salmon in the Broughton Archipelago for measurable Sea Lice transmission to the juvenile cohort in the face of such dispersal. Perhaps Sea Louse recruitment is an infrequent event between free-ranging salmon, and our sample size was too small to capture it. Perhaps the duration of exposure to adult Pink Salmon was not long enough or the dynamic of juvenile and adult salmon travelling in opposite directions with juveniles along the shoreline and adults mid-channel suppressed copepodid recruitment. Perhaps some small increase in parasite load did occur, but natural variability and small sample size left us with insufficient statistical power to detect this small effect above the ambient levels in the Broughton Archipelago. Morton et al. (2004) reported that in areas without salmon farms juvenile Pink Salmon were not infested with *L. salmonis*. Therefore, it is possible that in the absence of farm salmon the 4.8% prevalence we found on juvenile salmon in August and September could have been entirely or partially in response to arrival of the wild adult Pink Salmon.

Likely our inability to detect response in Sea Louse populations to returning adult Salmon was some combination of these. The lack of observed recruitment of new Sea Lice suggests that some mechanism has evolved to suppress transfer of lice from returning adults to out-migrating smolts in a naturally functioning ecosystem. Because Sea Louse pathogenicity is host-size dependant, protecting the smaller salmon from *L. salmonis* infestation would have clear evolutionary benefits, particularly for the Pink and Chum salmon that go to sea smaller than any other salmonid.

If exposure to abundant Sea Lice infested wild adults did not trigger a measurable increase in Sea Lice loads on juvenile Pink and Chum salmon, then this leaves the other, less abundant (if at all present), overwintering inshore wild salmon species poor candidates for explaining the enormous and recent spring *L. salmonis* outbreaks in the Broughton Archipelago.

Clearly, more extensive research is urgently needed. In the meantime, our study suggests that wild Pink Salmon do not appear to be the primary source of the high Sea Lice infestations reported on wild juvenile Pink and Chum salmon in the Broughton Archipelago. They may, however, be the primary source infecting the farm salmon and thus pose a risk to the industry. We conclude the most obvious source of *L. salmonis* on juvenile Pink and Chum salmon in the Broughton Archipelago is the stationary population of several million, farmed Atlantic Salmon.

Butler, Matthew J., Warren B. Ballard, and Heather A. Whitlaw. 2006. Physical characteristics, hematology, and serum chemistry of free-ranging Gray Wolves, *Canis lupus*, southcentral Alaska. Canadian Field-Naturalist 120(2): 205-212.

Examination of morphometric characteristics and blood parameters has become a widely used tool for assessing the physiological and nutritional status of wild and captive animals. During 1976 through 1984, 155 Gray Wolves (*Canis lupus*) were chemically immobilized in south-central Alaska. Of those, we obtained physical measurements from 132 and blood samples from 121 individuals. Also, 208 carcasses of harvested and dead radiocollared Wolves were weighed and measured. We obtained blood samples from three of the fresh carcasses. We measured age, body weight, skull length and width, and upper and lower canine length. We analyzed blood serum for Ca, P, Fe, chlorides, creatinine, glucose, lactic dehydrogenase, alkaline phosphatase, glutamic oxalic transaminase, triglyceride, beta globulin, serum urea nitrogen, and uric acid. We obtained packed cell volume and hemoglobin values from whole blood. We classified samples by season, sex, and age. Seasonal differences were observed for physical measurements, packed cell volume, alkaline phosphatase, and serum urea nitrogen. Age differences were observed for physical measurements, hemoglobin, packed cell volume, alkaline phosphatase, P, Ca, creatinine, serum urea nitrogen, and percent femur bone marrow fat. However, differences among sexes were observed for physical measurements only. These data provide a baseline for physical condition, hematology, and serum chemistry for free-ranging Gray Wolves.

Key Words: Gray Wolf, *Canis lupus*, blood, chemistry, hematology, measurements, physical, serum, Alaska.

Examination of morphometric characteristics and blood parameters has become a widely used tool for assessing the physiological and nutritional status of wild and captive animals (e.g., LeResche et al. 1974; Seal and Mech 1983; DelGiudice et al. 1987; Franzmann and Schwartz 1988). Although baseline hematology and serum chemistry values for many species of captive animals exist, baseline values for free-ranging animals are also necessary to properly interpret data. It is also important to understand how factors such as age, sex, and season influence hematology and serum chemistry values.

Hematology and serum chemistry of captive Gray Wolves (*Canis lupus*) has been studied and described by Fox and Andrews (1973) and Constable (1998) in Alaska, Seal and Mech (1983) and DelGiudice et al. (1987) in Minnesota, Pospíšil et al. (1987) in the Czech Republic, and Drag (1995) in Missouri. Seal et al. (1975) and DelGiudice et al. (1991) in Minnesota, Messier (1987) in Quebec, and Constable et al. (1998) in Alaska studied and described hematology and serum chemistry of free-ranging Gray Wolves. Mech et al. (1984) reported changes in hematology and serum chemistry of a female Gray Wolf recuperating from near starvation in Minnesota. However, little baseline data exist for age, sex, and season for free-ranging Gray Wolf populations. The purpose of our study was to describe physical characteristics and report baseline hematology and serum chemistry values for age, sex, and season in free-ranging Gray Wolves of south-central Alaska.

Study Area

The study was conducted in an area of approximately 45 000 km^2, known as Alaska Game Management Unit 13, located approximately 125 km northeast of Anchorage, Alaska. The area was bisected by three major river systems including the Copper, Nelchina, and Susitna rivers. Primary prey species were Moose (*Alces alces*) and Barren-ground Caribou (*Rangifer tarandus granti*). Alternate prey species included Dall Sheep (*Ovis dalli*), Beaver (*Castor canadensis*), and Snowshoe Hare (*Lepus americanus*). Climate, topography, and other important aspects of the study area were described by Ballard et al. (1987, 1991b). Gray Wolf densities during this study ranged from 10.3/1000 km^2 in autumn 1975 to 2.6/1000 km^2 in spring 1982 (Ballard et al. 1987). Mean annual litter size in November ranged from 3.7 to 7.3 pups. The Wolf population was heavily exploited by humans (i.e., >40% of population) during the course of this study (Ballard et al. 1987).

The reference values we present here occurred during a period when both Moose and Caribou populations were increasing. Moose densities were highly variable in the study area and averaged about 603 to 741/1000 km^2 (Ballard et al. 1991b) and the population increased at a finite rate of increase of 1.03 to 1.06 annually (Ballard et al. 1986). Caribou populations during this time period increased from approximately 10 000 in 1976 to about 25 000 in 1984 (Bergerud and Ballard 1988). Winter conditions as reflected by snow depths were relatively moderate during this

time period except during 1978-1979 which was classified as severe (Ballard et al. 1991b).

Methods

We captured Gray Wolves for radiocollaring by darting them from a helicopter during 1976 through 1984 using methods described by Ballard et al. (1982, 1991a). We immobilized Wolves with phencyclidine hydrochloride, etorphine hydrochloride, or a combination of zolzepam hydrochloride and tiletamine hydrochloride following dosages and methods described by Ballard et al. (1982, 1991a). Induction times averaged 7.2 minutes (Ballard et al. 1991a). After immobilization each Wolf was radiocollared, weighed, sexed, eartagged, bled, and a number of physical measurements were recorded on standardized forms. Physical measurements included skull length (SL) and width (SW), and upper (UCL) and lower canine length (LCL). We measured canine length from the edge of the gum line to the tip of the tooth. Skull and tooth measurements were taken with calipers and recorded to the nearest mm.

Hunters and trappers were paid $10 (U.S.) per skinned Wolf carcass. Carcasses were weighed (CW) and then kept frozen until examined. Skulls were not boiled and cleaned before measuring to maintain similarity with live Wolf measurements. Also, the effects of freezing carcasses on physical measurements were likely minimal. We determined percent femur bone marrow fat (MF) by the dry weight method (Neiland 1970). Because this Wolf population was heavily exploited (Ballard et al. 1987) we were able to do comparisons with many individuals that had been radiocollared and harvested within the same year.

We collected blood samples from saphenous veins using the B-D Vacutainer system (Becton-Dickenson Co., Rutherford, New Jersey, USA). Generally blood was taken within 15 minutes of induction time and serum was separated each evening. Only three blood samples were collected from carcasses. Those samples were obtained within 15 minutes of harvest. We used one EDTA tube to preserve whole blood. Packed cell volume (PCV) was determined with uncoagulated whole blood using a microhematocrit centrifuge (Triac, Clay-Adams Co., Parisppany, New Jersey, USA) while hemoglobin (Hb) was estimated with an AO Hb-Meter (American Optical, Buffalo, New York, USA). Clotted blood was centrifuged within 36 h of collection and serum was then stored frozen at -17°C. We sent frozen serum to Pathologist Central Laboratory, Seattle, Washington, USA, where it was analyzed for the following via an auto-analyzer: calcium (Ca), phosphorous (P), iron (Fe), chlorides (CHL), creatinine (CRE), glucose (GLU), lactic dehydrogenase (LDH), alkaline phosphatase (SAP), glutamic oxalic transaminase (SGOT), triglyceride (TRI), serum urea nitrogen (SUN), and uric acid (UA). Protein fractions were determined by standard protein electrophoresis for beta globulin (BEG).

Because of unbalanced cells in our analyses, we pooled years, sorted blood and physical measurements by sex, age, and season, and conducted multiple analyses of variance. We conducted post-hoc comparisons with a Scheffe test (Sokal and Rohlf 1995). We determined correlations among variables by Spearman's rank correlation (Conover 1980). We classified ages as pup (≤12 months), yearling (13 to 23 months), and adult (≥24 months), while seasons were divided into autumn (September through November), winter (December through February), spring (March through May), and summer (June through August). Differences were considered significant when $P < 0.05$ unless otherwise specified.

Results

We immobilized 155 individual Gray Wolves during 1976 through 1984. From that total, we obtained 121 blood samples ($n = 121$ serum samples, $n = 117$ whole blood samples) and 132 live body weights (BW). Due to low sample sizes, we excluded yearling and summer data from the analyses. In addition, we weighed and measured a total of 208 carcasses. We obtained three blood samples from fresh carcasses ($n = 3$ serum samples, $n = 2$ whole blood samples).

Physical Characteristics

Mean BW differed by season ($F = 26.121$, 2 df, $P < 0.001$), sex ($F = 37.084$, 1 df, $P < 0.001$), and age ($F = 147.890$, 1 df, $P < 0.001$), and there were significant interactions between season and age ($F = 15.665$, 2 df, $P < 0.001$), and among season, sex, and age ($F = 3.231$, 2 df, $P = 0.043$). Lowest BW occurred for pups during autumn, while highest BW occurred for adult males during autumn and winter (Table 1). Adult males had higher BW than male pups during autumn and winter; adult females had higher BW than female pups during autumn and spring (Table 1). Body weights were not different between adult males and adult females among seasons (Table 1). Body weights between male and female pups was only significantly different during spring (i.e., males were heavier; Table 1). Body weights of male pups increased with seasons (i.e., over the course of the biological year); both winter and spring BW were higher than autumn weights, although winter and spring were not different (Table 1). In addition, BW of female pups increased with season though female pups were significantly heavier in the spring than during autumn (Table 1).

Mean CW exhibited similar trends by sex, age, and season as BW although sample sizes were too small to evaluate post-hoc differences (Table 1). Season ($F = 4.849$, 2 df, $P = 0.009$), sex ($F = 6.665$, 1 df, $P = 0.011$), and age ($F = 24.849$, 1 df, $P < 0.001$) each had a significant effect on CW and there were significant interactions between sex and age ($F = 3.950$, 2 df, $P = 0.046$), and among season, sex, and age

TABLE 1. Mean physical measurements ± 1 standard error by season, sex, and age for free-ranging Gray Wolves in south-central Alaska during 1976 through 1984. Sample size denoted in parentheses.

Physical measurements	Age	Sex	Season		
			Autumn	Winter	Spring
Live-body weight (kg)	Pup	Male	26.2 ± 2.3 (8)	37.9 ± 1.4 (10)	41.3 ± 1.4 (16)

		Female	1.9 ± 0.1 (5)	2.3 ± 0.1 (45)	2.3 ± 0.1 (10)
	Adult	Male	2.8 ± 0.04 (6)	2.9 ± 0.1 (32)	3.0 ± 0.1 (7)
		Female	2.3 ± 0.3 (3)	2.5 ± 0.1 (25)	2.5 ± 0.04 (6)

($F = 4.105$, 1 df, $P = 0.018$). Lowest CW occurred for pups during autumn, while highest weights were for adult males during autumn and winter (Table 1).

There were significant differences in average SL by season ($F = 5.008$, 2 df , $P = 0.007$), sex ($F = 23.574$, 1 df , $P < 0.001$), and age ($F = 22.331$, 1 df , $P < 0.001$), and there were significant interactions between season and age ($F = 3.769$, 2 df , $P = 0.024$) and among season, sex, and age ($F = 3.874$, 2 df , $P = 0.022$). Lowest mean SL was for pups during autumn and highest mean SL was for adult males during autumn and winter (Table 1). Males had higher mean SL than females during each season (Table 1). Mean pup SL increased from autumn through spring (Table 1).

Mean SW differed by season ($F = 3.831$, 2 df , $P = 0.023$), sex ($F = 7.692$, 1 df , $P = 0.006$), and age ($F = 32.160$, 1 df , $P < 0.001$), and there was a significant interaction between season and age ($F = 4.582$, 2 df , $P = 0.011$). Mean male SW was greater than female SW for all seasons and ages (Table 1). There were no differences in average adult SW among seasons (Table 1). Also, mean pup SW increased by season during the first year of life (Table 1).

Mean UCL differed by season ($F = 5.257$, 2 df , $P = 0.006$), sex ($F = 19.804$, 1 df , $P < 0.001$), and age ($F = 26.872$, 1 df , $P < 0.001$), and there were no significant interactions. Mean UCL was lower during autumn than during either winter or spring (Table 1). Mean male UCL was greater than that of females (Table 1). Mean UCL for adults was greater than that for pups (Table 1). There was no significant difference in mean LCL by season ($F = 0.002$, 1 df , $P = 0.964$), sex ($F = 1.707$, 1 df , $P = 0.218$), or age ($F = 0.828$, 1 df , $P = 0.382$), and there were no significant interactions. Mean LCL was 2.3 ± 0.07 cm ($n = 18$). Body weight was also correlated with the other physical characteristics, MF, and PCV (Table 2).

Hematology

Mean Hb concentration differed by age ($F = 7.671$, 1 df , $P = 0.007$) and there was a significant interaction between age and season ($F = 3.876$, 2 df , $P = 0.024$); differences were between pups and adults during winter and autumn (Table 3). Mean pup Hb concentrations increased throughout the year, whereas adult Hb concentrations remained relatively constant during the year (Table 3).

Average PCV differed by season ($F = 6.015$, 2 df, $P = 0.003$) and age ($F = 29.083$, 1 df, $P < 0.001$), and there was a significant interaction between season and age ($F = 10.375$, 1 df, $P < 0.001$). Adults during autumn had higher mean PCV than all other groups by season and age (Table 3). Mean PCV did not differ between adults and pups in winter and spring (Table 3). Packed cell volume was also correlated with Hb and BW (Table 2).

Serum Chemistry

Mean SAP concentration differed by season ($F = 6.557$, 2 df, $P = 0.002$) and age ($F = 19.621$, 1 df, $P < 0.001$), and there was a significant interaction between age and season ($F = 5.189$, 2 df, $P = 0.007$). Mean SAP concentration appeared greater in pups than adults during autumn, winter, and spring (Table 3). However, only during autumn were SAP concentrations significantly different between pups and adults (Table 3). Among pups, autumn and winter SAP concentrations were higher than spring, but only the autumn–spring comparison was significant. Among adults, seasonal

TABLE 2. Correlations among physical characteristics, hematology, and serum chemistry values for free-ranging Gray Wolves in south-central Alaska during 1976 through 1984.

	Characteristics	r_s	n	P
Body weight	Carcass weight	0.954	23	<0.001
	Skull length	0.665	67	<0.001
	Skull width	0.639	62	<0.001

TABLE 3. Mean blood characteristics ± 1 standard error by season and age for free-ranging Gray Wolves in south-central Alaska during 1976 through 1984. Sample size denoted in parentheses.

Blood characteristics	Age	Season Autumn	Winter	Spring
Alkaline phosphatase (IU/L)	Pup	177.8 ± 33.1 (10)	141.9 ± 32.0 (15)	65.0 ± 6.9 (29)
	Adult	49.3 ± 6.1 (21)	90.0 ± 38.8 (12)	49.8 ± 6.7 (37)
Urea nitrogen (mg/dL)	Pup	26.2 ± 2.5 (10)	25.4 ± 6.0 (15)	46.1 ± 4.1 (29)
	Adult	45.4 ± 4.2 (21)	37.6 ± 7.4 (12)	52.9 ± 3.4 (37)
Hemoglobin (g/dL)	Pup	17.9 ± 0.4 (8)	18.0 ± 0.8 (10)	19.1 ± 0.2 (26)
	Adult	19.9 ± 0.07 (21)	18.9 ± 0.6 (11)	19.0 ± 0.3 (29)
Packed cell volume (%)	Pup	47.8 ± 2.2 (7)	44.2 ± 1.2 (12)	49.0 ± 1.1 (32)
	Adult	63.6 ± 2.0 (23)	55.1 ± 1.8 (11)	49.7 ± 1.3 (34)

SAP concentrations were not significantly different (Table 3). Serum alkaline phosphatase was also correlated to age, P, and Ca (Table 2).

Mean SUN concentration differed by season ($F = 6.746$, 2 df, $P = 0.002$) and age ($F = 10.382$, 1 df, $P = 0.002$), and there were no significant interactions. Mean SUN concentration was higher during spring than in winter; autumn SUN concentration was not different from spring or winter (Table 3). Mean adult SUN concentration was higher than that of pups, regardless of season or sex (Table 3).

Mean P ($F = 6.595$, 1 df, $P = 0.012$), Ca ($F = 6.036$, 1 df, $P = 0.016$), and CRE ($F = 4.189$, 1 df, $P = 0.043$) concentrations differed by age with no significant interactions. Pup P concentrations were higher than adults, regardless of season or sex, as were Ca concentrations (Table 4). Mean adult CRE concentration was higher than that of pups, regardless of season or sex (Table 4). There were no significant differences in mean values of BEG, CHL, GLU, Fe, LDH, SGOT, TRI, or UA by season, sex, or age, and there were no significant interactions (Table 5). Measures of BEG were also correlated with LDH concentrations (Table 2).

Bone Marrow Fat

Mean MF differed by age ($F = 5.062$, 1 df, $P = 0.027$). Mean pup MF was less than adult MF (Table 4). There were no differences in mean MF by season ($F = 0.351$, 1 df, $P = 0.555$) or sex ($F = 0.000$, 1 df, $P = 0.989$) and there were no significant interactions. Percent bone marrow fat was also correlated to BW, CW, SL, SW, and UCL (Table 2).

Discussion

Average BW of free-ranging Gray Wolves in south-central Alaska was greater than captive Gray Wolves in Minnesota (VanBallenberghe and Mech 1975; Seal and Mech 1983; Mech 2006) probably reflecting subspecies differences (Mech 1970). The relationship between CW and BW may allow managers to gain reliable biological data from harvested individuals. Also, the relationship between BW and MF may allow biologists to infer condition based upon BW.

Pup and adult Hb concentrations were in the upper range of values reported for free-ranging (Seal et al. 1975; Messier 1987; DelGiudice et al. 1991) and captive (Seal and Mech 1983; DelGiudice et al. 1987;

Pospíšil et al. 1987) Gray Wolves. In addition, we observed a correlation between Hb and BW and it has been suggested Hb concentration is a good indicator of physical condition (Franzmann and LeResche 1978; Messier 1987; Franzmann and Schwartz 1988). However, Harlow and Seal (1981) observed little change in Hb concentrations in food-deprived captive Badgers (*Taxidea taxus*). Perhaps, lower Hb concentrations in pups are indicative of a dietary difference due to social status. Seal and Mech (1983) observed low Hb concentrations during July and August in captive Gray Wolves. They also noted reduced BW during this period. Also, lower Hb concentrations in winter than in spring were reported by Thomas and Kittrell (1966) for German shepherds. Changes in Hb concentrations by season have also been observed in female Black Bears (*Ursus americanus*) (Franzmann and Schwartz 1988) and female White-tailed Deer (*Odocoileus virginianus*) (DelGiudice et al. 1992). However, our Hb data were unaffected by season and we observed comparable Hb concentrations in summer (18.6 ± 1.4 g/dL, $n = 5$). Franzmann and LeResche (1978) did not observe a seasonal effect on Hb concentrations in Moose. Perhaps, the reduced BW and Hb concentrations observed by Seal and Mech (1983) during summer can be attributed to a physiological response to greater summer heat in Minnesota. However, the elevation of Alaska Game Management Unit 13 lies above 1,220 m and the research conducted by Thomas and Kittrell (1966) suggested increased elevation resulted in increased Hb concentrations in German shepherds. Thus, perhaps, high Hb concentrations in south-central Alaskan Gray Wolves may have been due to higher elevation.

Thomas and Kittrell (1966) also observed increased elevation resulted in increased PCV levels in German shepherds. Perhaps, this explains why mean PCV in south-central Alaskan Wolves was greater than values reported by DelGiudice et al. (1991) in free-ranging Minnesota Wolves. Similar PCV values have been observed in free-ranging (Smith and Rongstad 1980) and captive (Gates and Goering 1976; Rich and Gates 1979) Coyotes (*Canis latrans*).

Franzmann and LeResche (1978) and Franzmann and Schwartz (1988) suggested PCV was a good indicator of physical condition. We also observed a seasonal effect on PCV. Autumn PCV (59.9 ± 2.0%, $n = 30$) was greater than spring (49.4 ± 0.8%, $n = 66$) and winter (49.4 ± 1.6%, $n = 23$). This suggests Wolves in Alaska Game Management Unit 13 were in their best physical condition in autumn. However, different seasonal patterns were observed by Thomas and Kittrell (1966) in German shepherds: lower PCV in winter than spring. Seasonal changes in PCV have also been observed in female Black Bears (Franzmann and Schwartz 1988), female White-tailed Deer (Bahnak et al. 1979; DelGiudice et al. 1992), and Moose (Franzmann and LeResche 1978). Female White-tailed Deer in Minnesota exhibited two peaks (February-March and October-November) in BW and PCV (DelGiudice et al. 1992). However, PCV levels in Michigan female White-tailed Deer reached their lowest levels in July through September when those animals reached slightly lower weights (Buhnak et al. 1979). Female Black Bear exhibited a decline in PCV during summer and, though not significant, an increase during autumn (Franzmann and Schwartz 1988). Franzmann and LeResche (1978) observed greater PCV during June through October in Moose.

TABLE 4. Mean characteristics ± 1 standard error by age for free-ranging Gray Wolves in south-central Alaska during 1976 through 1984. Sample size denoted in parentheses.

Characteristics	Age	Mean ± standard error (n)
Phosphorous (mg/dL)	Pup	5.8 ± 0.3 (54)
	Adult	4.4 ± 0.4 (69)
Calcium (mg/dL)	Pup	9.6 ± 0.3 (54)
	Adult	8.9 ± 0.3 (70)
Creatinine (mg/dL)	Pup	0.9 ± 0.04 (54)
	Adult	1.1 ± 0.1 (70)
Marrow fat (%)	Pup	79.6 ± 16.9 (64)
	Adult	87.0 ± 9.2 (44)

TABLE 5. Mean serum chemistry values ± 1 standard error for free-ranging Gray Wolves (season, sex, and age combined) in south-central Alaska during 1976 through 1984. Sample size denoted in parentheses.

Serum chemistry values	Mean ± standard error (n)
Iron (umol/L)	47.4 ± 4.5 (71)
Chlorides (mmol/L)	161.1 ± 4.0 (124)
Glucose (mg/dL)	118.7 ± 7.4 (122)
Lactic dehydrogenase (IU/L)	306.7 ± 22.7 (123)
Glutamic oxalic transaminase (IU/L)	226.5 ± 23.8 (120)
Triglyceride (mg/dL)	51.8 ± 5.8 (124)
Beta gobulin (g/dL)	1.0 ± 0.06 (93)
Uric acid (mg/dL)	1.3 ± 0.09(114)

Our SUN data was greater than or in the upper range of values reported for free-ranging Wolves (Seal et al. 1975; Messier 1987), captive Wolves (Seal and Mech 1983; Drag 1995), captive Coyotes (Rich and Gates 1979; Dunbar and Giordano 2002), and free-ranging Coyotes (Smith and Rongstad 1980). However, other studies have reported concentrations similar to this study. DelGiudice et al. (1987) reported average SUN concentrations of well-fed captive Gray Wolves between 37.5 and 44.4 mg/dL. However, during fasting those concentrations were reduced to a range of 12.0 to 19.8 mg/dL. Another study conducted on free-ranging Wolves ($n = 11$) in the Yukon-Charley Rivers National Preserve, Alaska (Constable et al. 1998), reported SUN concentrations (46.2 mg/dL) similar to our observations.

Higher dietary intake of protein is indicated by higher SUN concentrations as described for Dogs (Lane

and Robinson 1970; Bressani and Braham 1977), White-tailed Deer (Seal et al. 1972; Bahnak et al. 1979), and Pronghorn (*Antilocapra americana*) (Seal and Hoskinson 1978). We observed lower SUN concentrations in pups, suggesting a dietary difference, perhaps, due to social status. We also observed seasonal differences in SUN concentrations. Urea nitrogen was greatest during spring, intermediate in autumn, and lowest in winter, suggesting greatest intake of protein during spring. This may be indicative of increased Moose vulnerability due to reduced Moose group size and increased number of calves (Ballard et al. 1991b). Though sample size was low ($n = 5$), SUN concentration during summer was relatively high (41.8 + 6.1 mg/dL) which was comparable to well-fed captive Wolves (DelGiudice et al. 1987). Seasonal variation has also been observed in Black Bears (Franzmann and Schwartz 1988), female White-tailed Deer (Bahnak et al. 1979; DelGiudice et al. 1992), Santa Cruz Island Spotted Skunks (*Spilogale gracilis amphiala*) (Crooks et al. 2003), Santa Cruz Island Foxes (*Urocyon littoralis*) (Crooks et al. 2000), and Son Joaquin Kit Foxes (*Vulpes macrotis mutica*) (McCue and O'Farrell 1992). For each of these species, peak SUN concentrations appeared to coincide with the most productive seasons.

Phosphorus concentrations were similar to those reported for free-ranging (Seal et al. 1975; Messier 1987; Constable et al. 1998) and captive (Drag 1995; Constable et al. 1998) Wolves. Our analyses suggested pup P concentrations were higher than adults. Messier (1987) observed lower P concentrations in adults as well. Calcium concentrations were similar to reported values (DelGiudice et al. 1987 in addition to those cited above). However, no other Wolf study reported pup Ca values but we observed pup Ca concentrations were higher than adults. We also observed higher SAP concentrations in pups than adults. This has been observed in Gray Wolves (Messier 1987), Coyotes (Smith and Rongstad 1980), and Dogs (Pickrell et al. 1974). High SAP concentration is indicative of bone formation and osteoblast differentiation (Searcy 1969). Serum alkaline phosphatase was also correlated to age, P, and Ca. Interestingly, of adult SAP values, 11.4% (all male and sampled in different seasons) were above the lower 95% confidence interval for pup SAP values. High SAP concentration has been associated with mammary tumors in dogs (Karayannopoulou et al. 2003), mast cell disease in humans (Pardanani et al. 2002), pregnancy in animals (Stockham and Scott 2002; Bain 2003), healing of broken bones (Searcy 1969), and other diseases in Dogs (Cornelius 1980). Thus, SAP concentration may be used to identify injured or diseased individuals.

Conclusions

New patterns in physical condition, hematology, and serum chemistry were identified for Gray Wolves. Pups appeared to be under greater nutritional stress than adults as suggested by reduced MF, PCV, and SUN and Hb concentrations in pups. We also confirmed established differences in SAP concentrations between adults and pups. However, abnormally high SAP concentrations were observed in a portion of the adult male Wolves, perhaps, identifying injured or diseased individuals. High PCV in autumn suggested Gray Wolves of this population were in their best physical condition during autumn. High SUN concentrations in spring suggested these Wolves were under little nutritional stress during spring and appeared to be on a good nutritional plane during summer, as suggested by relatively high summer SUN concentrations. Also, high Hb concentrations and PCV in this population were probably a result of higher elevation.

These data, classified by season, sex, and age, provide a baseline physical condition, hematology, and serum chemistry for free-ranging Gray Wolves with a relatively high and increasing prey base in south-central Alaska. However, more information on yearlings and summer is needed to properly understand physical condition, hematology, and serum chemistry of this Gray Wolf population. Although we found several correlations among BW, Hb, PCV, MF, and several other variables, a number of measurements should be used to assess physical condition.

Acknowledgments

The study was funded by several Alaska Federal Aid to Wildlife Restoration Projects and the Alaska Power Authority. Publication costs were paid by the Department of Natural Resources Management, Texas Tech University. We gratefully acknowledge L. Aumiller, T. Balland, A. W. Franzmann, C. L. Gardner, P. Hessing, L. Metz, R. Toby, J. Westlund, J. Whitman, and many other employees of the Alaska Department of Fish and Game for their assistance with the collection and processing of specimens. Also, two anonymous reviewers provided valuable comments and suggestions on earlier drafts of the manuscript. This is Texas Tech University, College of Agricultural Science and Natural Resources technical publication T-9-1021.

Demarchi, Mike W. 2006. Are Lesser Snow Geese, *Chen caerulescens caerulescens* exceeding the carrying capacity of the Fraser River delta's brackish marshes? Canadian Field-Naturalist 120(2): 213-224.

Brackish marshes of the Fraser River delta provide important habitats for such high-profile animals as White Sturgeon (*Acipenser transmontanus*), Pacific Eulachon (*Thaleichthys pacificus*), Pacific salmon (*Oncorhynchus* spp.), Western Sandpiper (*Calidris mauri*), and Lesser Snow Goose (*Chen caerulescens caerulescens*), the latter comprising the "Fraser Skagit" segment of the Wrangel Island (Russia) population. This study assessed whether the current numbers of Snow Geese are exceeding the carrying capacity of brackish marshes in the Fraser River delta. Simulation modelling predicts that those marshes are presently capable of supporting ~17 500 Snow Geese—a value that is greatly exceeded by the numbers of geese that have over-wintered there in recent years (~80 000 in 2004-2005). The Pacific Flyway Council's target 3-y average population and segment sizes of 120 000 and 50 000 - 70 000, respectively, were set without considering the carrying capacity of natural wintering habitats, the potential impacts of too many geese on upland agriculture, or implications for hazards to civilian aircraft at Vancouver International Airport. The modelled results of the present study suggest that the Fraser River delta can sustain the current numbers of Snow Geese that stage or winter there only if those birds also forage in agricultural and refuge fields—a relatively recent phenomenon that likely bolstered the Snow Goose population. Over-use by Snow Geese can degrade the productivity and habitat quality of marshes. There is documented evidence that some key plant species (e.g., *Scirpus americanus*) of the brackish marshes of the Fraser River delta are well below their biomass potential (~15%), primarily because of grubbing by Snow Geese. Other species that depend on this brackish environment as well as human interests in the Fraser River delta may be adversely affected by an overabundance of Snow Geese. The future effectiveness of hunting as a primary means of population regulation is questioned.

Key Words: Lesser Snow Goose, *Chen caerulescens caerulescens*, American Three-square Bulrush, *Scirpus americanus*, brackish marsh, carrying capacity, Fraser River delta, bird strike, British Columbia.

The recent dramatic increase in numbers of the mid-continent (North America) Lesser Snow Goose (*Chen caerulescens caerulescens*) has attracted considerable attention—mainly because of the habitat degradation it has caused (e.g., Kerbes et al. 1990; Williams et al. 1993; Ankney 1996). Consumption of agricultural foods (which may be more abundant and contain higher fractions of metabolizable energy than native brackish-marsh plants) and a network of refugia are thought to have contributed to substantial increases in some North American populations of Lesser Snow Geese by improving overwinter survival (Ankney 1996; Jefferies 1997). Although the bird community that winters on the Fraser River delta contains many species of grazing waterfowl, the large amount of rhizome biomass consumed annually by Lesser Snow Goose (Boyd 1995) means it is potentially a keystone species there as it is elsewhere (e.g., Kerbes et al. 1990).

Many Snow Geese that breed on Wrangel Island (Russia) use the Fraser River delta as staging or wintering habitat between October and April (Subcommittee on White Geese 1992*; Boyd 1995; Pacific Flyway Council 2006*). They forage in brackish marshes of the Fraser River delta, primarily on rhizomes of American Three-square Bulrush (*Scirpus americanus*) and shoots of Lyngbei Sedge (*Carex lyngbyei*). J. P. Hatfield (personal communication, cited in Campbell et al. 1990) noted that Snow Geese began foraging in agricultural fields on the Fraser River delta in 1977. The number of Snow Geese using those fields rose from 2000 in the early 1980s to between 20 000 and 30 000 in the 1990s (Boyd 1995; Canadian Wildlife Service et al. 1999*). The Canadian Wildlife Service (CWS) and local farmers actively enhance the Alaksen National Wildlife Area (ANWA) on Westham and Reifel islands in the Fraser River delta for wintering Snow Geese and other waterfowl. Fields within the ANWA are planted with crops to provide the birds with supplemental feed (Pacific Flyway Council 2006*).

Because Snow Geese and other grazing waterfowl can affect private agricultural fields outside the ANWA by consuming grass, crops, or crop residue such as corn and potatoes, and by altering surface-water drainage, the "Greenfields Program" administered by the Delta Farmland and Wildlife Trust (DFWT) was established in 1990. The goal of that program is to spread waterfowl impacts over a larger area, thereby lessening their severity in any one given area (Smith 1996*). The program encourages farmers to plant cover crops for soil conservation and provide forage for over-win-

tering waterfowl. The costs of these cropping practices are shared among farmers, conservation societies, and government bodies.

Snow Geese that overwinter on the Fraser River delta are managed according to the Pacific Flyway Council's 2006 management plan (Pacific Flyway Council 2006*) which is a revised version of the 1992 plan (Subcommittee on White Geese 1992*). Although the overall Wrangel Island population target of 120 000 birds (3-year average) remains the same between the 1992 and 2006 plans, the target size of the Fraser-Skagit segment (also referred to as "subpopulation" or "flock") target was increased to a range of 50 000-70 000 birds in the 2006 plan. According to the 1992 plan, the segment target was a minimum 3-year average of 35 000 birds. To achieve that, the ideal segment size had been identified to be between 30 000 and 60 000 birds (S. Boyd, personal communication). The historical size of the Wrangel Island population was considered when the goal was set, but some key factors were not: the carrying capacity of the Fraser and Skagit deltas, the possible impacts of Snow Geese on habitat quality and ecosystem function of the Fraser River delta, nor the possible impacts of Snow Geese on agriculture or air-safety. Under the 2006 plan, regulation of the Wrangel Island population is to occur by way of sport and subsistence hunting.

Burton (1977) concluded 30 years ago that the brackish marshes of the Fraser River delta would be damaged if the Fraser-Skagit segment exceeded 20 000 Snow Geese. The purpose of this study was to evaluate, by way of simulation modelling, recent numbers of Snow Geese in light of the carrying capacity of the brackish marshes in the Fraser River delta.

Study Area

The Fraser River sustains the largest delta on Canada's Pacific coast. The delta covers ~680 km^2 of aquatic and terrestrial areas, stretching 30 km from New Westminster westward to Sand Heads Lighthouse and from Point Grey southward to the international boundary (Butler and Campbell 1987). Brackish marshes occupy ~3% of the delta.

The Fraser River delta is a critical link in a series of migratory bird habitats along the Pacific Flyway between the arctic breeding grounds of North America and northeast Asia and wintering areas in southwestern North America, Central America, and South America. The delta supports some of the highest densities of wintering waterfowl, shorebirds, and raptors in Canada (Butler and Campbell 1987).

Brackish marshes of the Fraser River delta have evolved as a result of the interactions between the maritime conditions of the Pacific Ocean and the fresh water and sediment load of the Fraser River (Hutchinson 1982). Local tides are predominantly semidiurnal with a maximum range of ~5 m. The Fraser River is the largest river in British Columbia, with a mean annual flow of 3500 m^3/s. Eighty percent of the annual flow occurs during March to July (Hoos and Packman 1974, *cited in* Hutchinson 1982). Hutchinson (1982) divided the present brackish marshes of Lulu Island into three elevational zones: (1) low marsh—dominated by *Scirpus americanus* and *S. maritimus*; (2) middle marsh—dominated by *Carex lyngbyei*, *Triglochin maritimum*, and *S. maritimus*; and (3) high marsh—a community of *Agrostis exerata*, *Potentilla pacifica*, *Distichlis spicata*, and *Typha latifolia*.

Prior to dyking, the low elevations of much of the land near the western limit of the delta were subject to periodic flooding during spring freshet. Such flooding would have affected the delta's vegetation communities. Habitats of this area have been, and are heavily, modified by human activities. Although much of the Fraser River delta is used for agriculture, residential, commercial, and industrial developments are rapidly increasing at the expense of agricultural land-uses. Commercial greenhouse operations are increasingly replacing traditional field-based agriculture.

Much of the upland and foreshore areas of Reifel Island and Westham Island make up a wildlife sanctuary that is managed by the CWS. The sanctuary comprises 586 ha, of which 300 ha includes the federally owned ANWA that was designated a Ramsar site in May 1982 (Wetlands International, no date*). Approximately 410 ha of the sanctuary are in cultivated farmland. The adjacent George C. Reifel Refuge, initiated in the 1960s, consists of 400 ha of Crown land designated as a Migratory Bird Sanctuary under the Migratory Birds Convention Act of 1917.

Nearly 6000 ha in the municipality of Delta is used to produce vegetable crops and livestock. Of the cropland, nearly two-thirds is planted in vegetables such as potatoes, peas, beans, corn, pumpkins, cabbage, rutabagas. Hay fields, pasture, and corn silage represent more than one-quarter of the cropland on the delta. The remainder of the cropland on the delta is allocated to cereals and berries.

Methods

A map of the brackish marshes was prepared by digitally scanning colour air photos (1:24 000 scale) at high resolution and ortho-rectifying each photo by tying control points to those on a TRIM base-map (1:20 000 scale). Air photos from 18 September 1991 were deemed the best in terms of resolution, scale, date, season, and tide height. I. Hutchinson (personal communication) indicated that the brackish marsh profile has likely undergone very minor net changes since that time. Habitat polygons were digitized manually on-screen while viewing habitat features at various magnifications. The digital map upon which habitat calculations were made had a minimum resolution of 1:10 000. Small patches of *Scirpus* spp. near southwestern Sea Island were amalgamated because it was believed that the distribution of those plants had in-

creased since the photos were taken (S. Boyd, personal communication). Interpretations of habitat type and zonation in the Fraser River delta were aided by information from Yamanaka (1975), Moody (1978), and Hutchinson (1982). Although changes in the marsh communities have undoubtedly occurred since maps in those reports were produced, the visual patterns of intertidal plant zonation were expected to have changed insignificantly. All mapping was done using the GIS programs MapInfo and ArcView.

Estimates of Snow Goose numbers since 1987-1988 were obtained from Boyd (1995) and Pacific Flyway Council (2006*). The numbers of Snow Geese using agricultural fields were obtained from Boyd (1995) for the period 1987-1992, and from Canadian Wildlife Service et al. (1999*) for the period 1995-1998. Data on the Greenfields Program were obtained from Smith (1996*).

Because of variation and error inherently associated with parameters used in the analyses, a stochastic simulation model was developed. The model, run in MS Excel 98, incorporated published and unpublished data from several sources. Data in Imperial units (e.g., kcal) were converted to SI units (e.g., kJ). Stochasticity was incorporated in the model by randomly selecting values that were within the 95% confidence limits, or hypothesized range of some parameters.

The model in Appendix 1 was used to estimate the carrying capacity of the brackish marshes in the first half of the overwintering period ("autumn", versus the second half of the overwintering period: "spring"). Because the Fraser River delta experiences substantially more Snow Goose-days during autumn than in spring (Boyd 1995) and has less autumn habitat than spring habitat (as mapped in this study), I assumed that any habitat-imposed limitations on the geese would occur in autumn. Each simulation first calculated the metabolizable caloric value of the available *S. americanus*. From that value, the number of supportable Snow Goose-days was determined. In turn, Snow Goose-days (y) were used to estimate the size of the Fraser-Skagit segment (x) by using the inverse of the linear relation: $y = 47.764(x)$ ($P = 0.028$; $r = 0.89$; df = 5; y-intercept = 0) between "autumn" Snow Goose-days on the Fraser River delta and the size of the Fraser-Skagit segment as calculated from data presented in Boyd (1995). The y-intercept of this equation was set at 0 to account for segment sizes lower than those presented in Boyd (1995). Five thousand simulations were run.

A lack of data on two issues may have implications for the accuracy of the model's results, but because the parameters represented by these issues would not affect the model in a unidirectional manner, their implications are not viewed as necessarily troublesome. First, Burton et al. (1979) suggested that Snow Geese feed almost exclusively on rhizomes of *S. americanus* during autumn. In fact, however, Burton (1977, page 17) stated that Snow Geese strongly prefer both *S. americanus* and *S. paludosus* (the latter also known as *S. maritimus*). Unfortunately, as observed using gizzard contents, Burton (1977) could not differentiate between the cuticle reticulations of the rhizomes of the two species, thereby casting doubt on the accuracy of his conclusion about a dual food preference. Abundance of *S. maritimus* is about one-third that of *S. americanus* on the Fraser River delta (Yamanaka 1975). Second, the model assumes that all biomass grubbed by the Snow Geese is consumed by them. McIlhenny (1932; cited in Burton 1977) guessed that over-wintering Snow Geese in the southern United States rejected up to 10 times as much grubbed vegetation as they consumed. Burton (1977) felt that although some food rejection occurred on the Fraser River delta it did not likely approach those proportions.

Results and Discussion

Distribution, Abundance, and Carrying Capacity of Brackish Marshes in the Fraser River Delta

Autumn marsh habitat that is suitable for Snow Geese occurs in a narrow band along the western edge of the Fraser River delta's westernmost islands and near Brunswick Point (Figure 1). Most spring marsh habitat is similarly distributed. According to habitat mapping, the Fraser River delta contains 917.1 ha of "low marsh" habitat and 946.3 ha of "mid-high marsh" habitat in areas used by Snow Geese. Low marsh habitat is used by Snow Geese for "grubbing" bulrush rhizomes in the autumn period and mid-high marsh habitat is used in the spring for foraging on emergent sedges (Boyd 1995).

The results of autumn carrying capacity simulations of the Fraser River delta's brackish marshes are summarized in Figure 2. During autumn, brackish marshes can presently support a number of Snow Goose-days that is commensurate with a mean Fraser-Skagit segment size of 17 600 geese (range 7400-35 000). Numbers larger than this will exceed the calculated carrying capacity of brackish marshes during most years. According to the model there was only a 1.4% chance that >30 000 geese could be sustained by the brackish marshes (Figure 2). Those observations, and the conclusion that *S. americanus* biomass in the Fraser River delta is only ~15% of what it might support in the absence of Snow Goose grubbing (Boyd 1995), suggest that brackish marshes are either already over-grubbed or are at considerable risk of being over-grubbed.

Distribution and Abundance of Snow Geese on the Fraser River Delta

Numbers of Snow Geese in the Fraser-Skagit segment have been estimated from aerial photos of geese on the Fraser and Skagit river deltas (Subcommittee on White Geese 1992*; Boyd 1995; Pacific Flyway Council 2006*). Most use of the Fraser River delta occurs during early October to mid-January ("autumn") and from late February to mid-April ("spring"). Al-

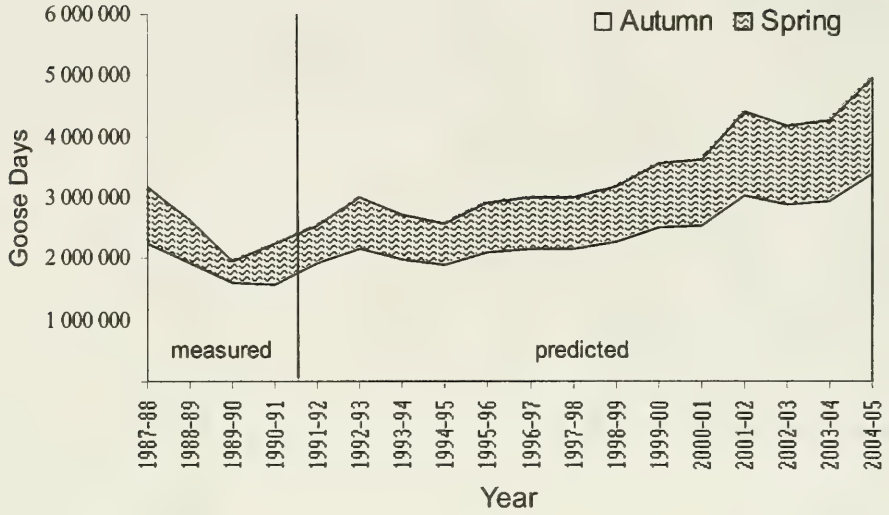

FIGURE 4. Stacked area chart showing measured and predicted number of Snow Goose-days on the Fraser River delta since 1987-1998. Data from 1987-1988 through 1991-1992 were measured by Boyd (1995). The remaining data were predicted using linear regression equations developed from data for the 1987-1988 through 1991-1992 period (Boyd 1995), and using population estimates (x values) from Pacific Flyway Council (2006*). Regression equations are as follows: (1) Autumn: y = 36.4(x) + 448 977 where y = autumn goose-days, and x = annual estimate of Fraser-Skagit segment ($P = 0.016$, $r = 0.94$, df = 4). (2) Spring: y = 22.7(x) - 221 987 where y = spring goose-days, and x = annual estimate of Fraser-Skagit segment ($P = 0.116$, $r = 0.78$, df = 4).

though geese occur on both deltas simultaneously during autumn and spring, most or all geese use the Skagit River delta for the four to five weeks between these periods. Since the winter of 1978-1979 (when the first photo counts on the Fraser and Skagit deltas were done) the Fraser-Skagit segment grew from ~27 000 birds (Pacific Flyway Council 2006*). Owing to high juvenile production and survival rates of Snow Geese, the Fraser-Skagit segment increased 3- to 4-fold in the late 1970s (Boyd 1995). Numbers of Snow Geese fluctuated in the 1980s then increased thereafter (Figure 3). Figure 3 shows an upward trend in the size of the Fraser-Skagit segment from 1978 through spring 2005 ($P < 0.001$; $r = 0.76$; df = 26). Recent surveys indicate that during the winter of 2004-2005 the segment was the highest ever recorded at ~80 000 birds (Pacific Flyway Council 2006*). From 1987-2005 the Fraser River delta sustained an estimated 2-5 million goose-days annually (Figure 4).

Farm fields apparently play an increasingly important role in the over-wintering ecology of the Fraser-Skagit segment of Snow Geese. The percentage of Snow Goose days spent on upland fields between 1987-1988 and 1991-1992 varied among years (Figure 5), but autumn-use, ranging between 7% and 30%, was typically much greater than spring use, which ranged from 0% to 20% (Boyd 1995). Although surveys of use of agricultural fields on Westham Island were conducted via ground counts from autumn 1995 through spring 1998 (cf. photo counts up to that point), the use of farm fields has increased in recent years. From 1995-1996 through 1997-1998, the use of farm fields on Westham Island (representing ~90% of all use of upland fields (S. Boyd, personal communication) ranged between 17% and 46% of the total number of goose days spent on the Fraser River delta in the autumn, and increased from 13% to 70% of such days in the spring (Figure 5). If foods in brackish marshes were being fully utilized, such a pattern would be expected if more goose-days were spent on the Fraser River delta. Indeed, Figure 4 shows a predicted increase in goose days over time and the linear relation between annual goose days on agricultural fields and size of the Fraser-Skagit segment is significant ($P = 0.002$, $r = 0.83$, df = 7); the lowest proportion of field-use occurred when the least number of goose days were spent on the Fraser River delta (1989-1990; Figures 4 and 5).

Snow Geese and the Brackish Marsh

The brackish marshes of the Fraser River delta are probably being over-utilized by Snow Geese. Model results indicate that the Fraser-Skagit segment exists at current levels only because the geese can also forage in upland fields. Maintaining numbers of Snow Goose above the carrying capacity of brackish marshes by way of providing supplemental feed on refuges and agricultural fields may degrade or continue to suppress the productivity of the brackish marshes. Boyd (1995) suspected that grubbing pressure by Snow Geese on

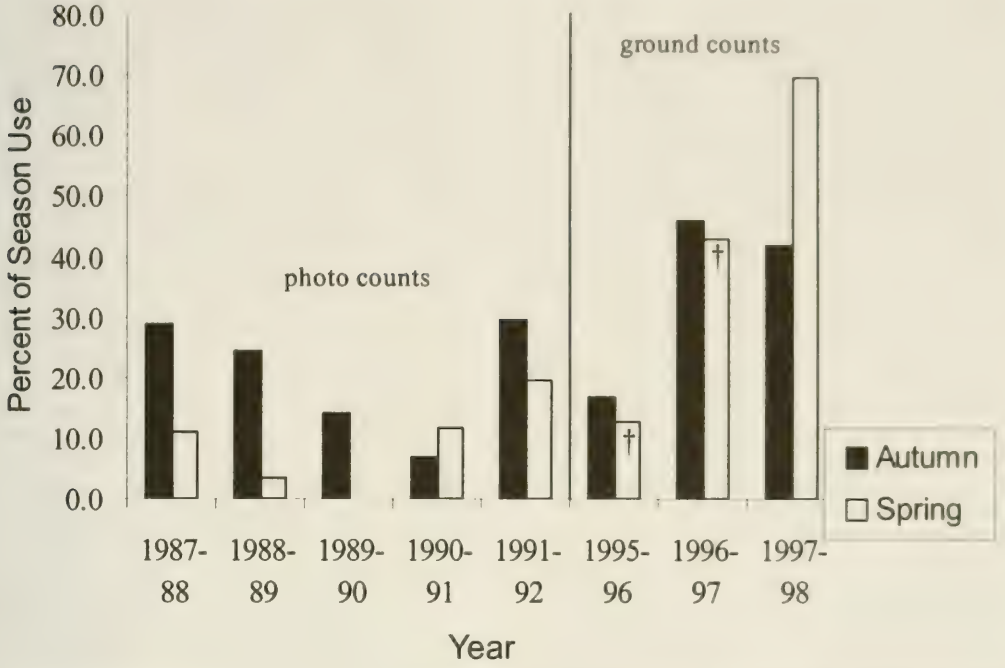

FIGURE 5. The estimated percentage of total Snow Goose-days on the Fraser River delta spent on agricultural fields during the "autumn" and "spring" seasons. Source: 1987-1992, Boyd (1995); 1995-1998, Canadian Wildlife Service et al. (1999*). †Spring use in 1995-1997 is likely underestimated because surveys ended several weeks before spring migration (departure).

parts of the Fraser Delta was contributing to a reversal in marsh succession. Boyd (1995) also speculated that the reason that production in the brackish marshes of the Skagit River delta was even lower (i.e., 10%) than the 15% figure reported for the Fraser River delta was because the Skagit River delta supported about twice as many goose-days as did the Fraser River delta during 1987-1992. Further, there is some concern that in recent years a greater proportion of the Wrangel Island population has been overwintering on the Fraser and Skagit deltas (Pacific Flyway Council 2006*).

If Snow Geese were excluded from all agricultural fields, including the sanctuary on Reifel and Westham islands, the segment would likely decline to a habitat-limited maximum size of ~15 000-20 000 birds. Although that scenario may be unrealistic, it is possible that changing land-uses and agricultural practices throughout the Wrangel Island population's winter range, in addition to changes in farmers' tolerance of Snow Geese in their fields, could direct even more foraging pressure onto brackish marshes. Regardless of farm-field availability, brackish marshes will always be vital for Snow Geese because during extended periods of freezing, the marshes are used exclusively (Boyd 1995). Use of marshes during cold weather likely reflects difficulties geese experience in obtaining food from the frozen or snow-covered soil of agricultural fields.

Snow Geese and Agricultural Fields

Forage from agricultural fields has contributed to the improved survivorship and subsequent population growth of Snow Geese in other parts of North America (Ankney 1996; Jeffries 1997). Possible reasons for the onset of, and increased use of, upland fields by Snow Geese on the Fraser River delta are not known with certainty, but it is plausible that rapid increases in the Snow Goose population during the late 1970s were largely responsible (Figure 3).

Burton (1977) predicted that if the Fraser-Skagit Snow Goose segment expanded beyond ~20 000 birds, the brackish marshes of the Fraser River delta would be adversely affected. Although estimates of *S. americanus* biomass in the mid 1970s (Burton 1977) and in the early 1990s (Boyd 1995) are not directly comparable due to different sampling strategies, a general review of the datasets suggests that rhizome densities during the early 1990s likely approximated those during the mid 1970s. This suggests that the brackish marshes were already being used to capacity by Snow Geese prior to the onset of farm-field use. Unfortunately, there are no data documenting trends in *S. americanus* biomass immediately following the rise in Snow

Goose numbers and onset of field use in the late 1970s and early 1980s so it is not known whether *S. americanus* biomass declined under more foraging pressure then merely rebounded as incremental foraging pressure on the delta shifted to upland fields.

The increased use of agricultural fields by the geese supports the hypothesis that the brackish marshes alone could not sustain the increased foraging pressure that a rising Fraser-Skagit segment was putting on the Fraser River delta. If the geese could not meet their energetic demands in brackish marshes, they would have been forced to explore alternate food sources such as those in agricultural fields. Several lines of evidence support this hypothesis.

First, from the perspective of Snow Goose foraging habitat, agricultural production suitable for Snow Geese in the local area has probably declined since the 1970s, both in areal extent and crop type (Boyd 1995). So, contrary to what might be expected, little or no use occurred when agricultural habitats were better for Snow Geese. According to W. Temple (DWFT, personal communication), there is no evidence that agricultural changes on the Fraser River delta influenced the initial use of upland habitats by Snow Geese in the late 1970s and early 1980s. W. Temple (personal communication) indicated that crops that Snow Geese presently use were grown for many years before the birds started using them. In 1993, farming of corn, peas, and beans by commercial processors on the Fraser River delta was largely halted (W. Temple, personal communication); thereby further diminishing the area of agricultural fields suitable for foraging Snow Geese. This likely put increased foraging pressure on other fields, and perhaps, on the brackish marshes.

Second, *S. americanus* stands in the Fraser River delta are at about 15% of their biomass potential in the absence of grubbing by Snow Geese (Boyd 1995). This suggests that the brackish marshes are not producing vast amounts of unutilized rhizomatous foods. Assuming a "steady state" between rhizome production and consumption, as reported by Boyd (1995), brackish marshes are being fully utilized (even overutilized) by consumers such as Snow Geese.

Third, Snow Geese on the Fraser River delta exhibit a high degree of site fidelity (Burton 1977; Boyd 1995). Thus, the full or partial abandonment of an area could indicate decreased habitat suitability. A lack of food in the traditionally used brackish marshes is a plausible reason why Snow Geese explored upland feeding areas. Such exploratory behaviour was predicted by Burton (1977) before the segment increased and before agricultural fields were used by the geese.

Finally, speculation that changes to hunting seasons and hunting areas in the Fraser River delta forced Snow Geese to use upland fields beginning in the late 1970s is not supported. The existence of a waterfowl refuge on Reifel Island has conceivably provided Snow Geese with upland foraging opportunities free of hunting pressure since the 1960s. Further evidence that hunting did not precipitate field use by Snow Geese is provided by Trumpeter Swans (*Cygnus buccinator*); a protected (i.e., unhunted) species since the 1930s. Trumpeter Swans and Snow Geese have similar diets during winter (Boyd 1995; Carter 1997). Trumpeter Swans have also experienced substantial increases in over-wintering populations in recent years. Carter (1997) noted that as numbers of Trumpeter Swans wintering near southwestern British Columbia have increased since the early 1970s, there has been a recent shift in habitat use from brackish marshes to agricultural areas. G. Fowler (CVWMP, personal communication) indicated that the use of agricultural fields by Trumpeter Swans in the Comox Valley on Vancouver Island, British Columbia, began in the mid-1970s. The onset of swan use of upland habitats was unlikely a response to any refuge effects provided by fields, as hunting for other waterfowl continues to this day on the same farm fields used by swans. Further, if swans were seeking refuge, the Courtenay River estuary (their traditional brackish-marsh wintering ground that has been largely abandoned as a foraging area in favour of upland sites) should still be used for foraging because it has been a no-shooting area since 1994. The swans roost in the estuary, but minimal feeding occurs there (G. Fowler, personal communication).

Conclusions

Currently, the increasing numbers of Snow Geese wintering on the Fraser River delta (~80 000 in 2004-2005; Pacific Flyway Council 2006*) exceed the modelled autumn carrying capacity of the area's brackish marshes (~17 500) by a large margin. As a result, the geese are highly dependent on forage provided in nearby agricultural and refuge fields. Despite compelling evidence that Snow Geese were grubbing *S. americanus* biomass to ~15% of its biomass potential since at least the early 1990s (Boyd 1995) and a doubling of the Fraser-Skagit segment from 1995-2005, the 2006 management plan (Pacific Flyway Council 2006*) only states that increasing numbers of Snow Geese *may* be reducing the biomass and extent of *S. americanus*. The Pacific Flyway Council (2006* page 13) recommends researching the "trends in biomass and growth dynamics of American Bulrush, impacts of grubbing by Snow Geese on intertidal marshes, and the carrying capacity of the Fraser-Skagit." The current plan relies on hunting to regulate the Wrangel Island population once it exceeds a 3-y average of 160 000 birds (Pacific Flyway Council 2006* page 32). As society's values and interests have shifted, sales of migratory bird hunting permits and participation in waterfowl hunting in British Columbia have declined steadily from 1974-2003 (Environment Canada 2005*). Hunting opportunity on the Fraser River delta has also diminished over time. Consequently, it is questionable that managers will be able to rely solely on hunting as a tool to effectively manage Snow Geese on the Fraser delta in the future.

Given that the brackish marshes are currently being used to (present) carrying capacity, any further increases in the Fraser-Skagit segment will likely require: (1) a substantial increase in the production of *S. americanus* rhizomes, (2) a concomitant increase in the use of agricultural fields by the geese, (3) natural selection for lower adult body weights, and thus lower gross energetic demands, or (4) a combination of these. Recognizing the reduced production of the brackish marsh, Boyd (1995) recommended that consideration be given to increasing the productivity of *S. americanus* by applying fertilizer. However, unless fertilization results in a yield of rhizomes exceeding that which Snow Geese could potentially consume, there is no reason to believe that Snow Geese would not consume fertilizer-induced growth back down to the "steady-state". The current management plan (Pacific Flyway Council 2006*) does not identify a need to research ways of increasing the carrying capacity of the marsh as was recommended in the 1992 plan (Subcommittee on White Geese 1992*).

By serving as food for herbivores and detritivores and as structural habitat (cover) for fish and invertebrates, healthy brackish marshes in the Fraser River delta are integral to an ecosystem that supports such key animals as White Sturgeon, Pacific Eulachon, Pacific salmon, shorebirds, and Snow Geese among many others. Large numbers of Snow Goose have negative implications not only for the brackish marsh ecosystem, but also for human safety. Bird hazard evaluations have concluded that Snow Geese pose an extreme hazard to civilian aircraft at the Vancouver International Airport on Sea Island (Demarchi and Searing 1995*). Consequently, an aggressive Snow Goose control program is necessary each winter near Sea Island to mitigate that hazard.

A prudent approach to managing the Wrangel Island population of Lesser Snow Geese would, at a minimum, be sensitive to Snow Goose conservation, potential adverse effects of Snow Geese on the brackish marsh ecosystem, and the interactions between Snow Geese and agriculture, air-traffic safety, and other land uses in the Fraser River delta.

Acknowledgments

Many people made important contributions to this study and manuscript. Their assistance is greatly appreciated, but such assistance does not necessarily connote full agreement with the manuscript's conclusions. S. Boyd, Canadian Wildlife Service (CWS) provided important data and reviewed drafts of this manuscript. K. Moore and M. Porter, CWS, also provided important data (Canadian Wildlife Service et al. 1999). S. Smith, Delta Farmland and Wildlife Trust (DFWT), provided data. W. Temple, DFWT, provided information about agriculture. C. Levings, Department of Fisheries and Oceans and I. Hutchinson, Simon Fraser University, provided information and advice on brackish marshes in the Fraser River delta. R. Alisauskas, CWS, provided information on the current status of bioenergetic studies of Lesser Snow Geese and gave constructive feedback on the simulation model. R. Trost, U. S. Fish and Wildlife Service, provided information about the Pacific Flyway Management Plan. G. Fowler, Comox Valley Waterfowl Management Project, provided information about Trumpeter Swans in the Comox Valley. D. Kraege, U. S. Fish and Wildlife Service, reviewed drafts of this manuscript. S. Johnson and G. Searing, LGL Limited, contributed to the design of this assessment and reviewed a draft of this manuscript. R. Tamasi, LGL Limited, assisted with GIS and mapping. G. Glova, LGL Limited, reviewed a draft of this manuscript as did A. Erskine and an anonymous reviewer.

APPENDIX 1. Simulation model for the carrying capacity of the brackish marshes of the Fraser River delta for Lesser Snow Geese during the autumn. Model calculations were performed with MS Excel 98.

Row	Parameter	Units	Value (column C)	Source/Comment
2	Proportion juveniles (variable)	juvenile/adult	= RANDBETWEEN(0,5)/10	Boyd (1995)
3	Adult mean body weight	kg	2.357	McKelvey et al. (1989)
4	Juvenile mean body weight	kg	2.032	McKelvey et al. (1989)
5	Difference between juvenile and adult existence energy	kJ/d	209	King 1974 (cited in Frederick et al. 1987)
6	Existence energy at 0 C: Mean Adult	kJ/d	= (RANDBETWEEN(455,871))*C3-C5	Sedinger et al. (1995)
7	Existence energy at 0 C: Mean Juvenile	kJ/d	= (RANDBETWEEN(455,871))*C4	Sedinger et al. (1995)
8	Activity Increment above existence	variable coefficient	= RANDBETWEEN(11,17)/10	Taken as range of values between a "low" level of activity and the mean value from Table 7 of Frederick and Klaas (1982). Note: geese studied by Frederick and Klaas (1982) are believed to be more active than those on the Fraser River delta (S. Boyd, personal communication)
9	Metabolizible energy of *Scirpus americanus* rhizomes	kJ/kg	= RANDBETWEEN(5860,6700)	Burton et al. (1979)
10	*S. americanus* consumed: Adult Maintenance	kg/day	= C6/C9	Calculated
11	*S. americanus* consumed: Juvenile Maintenance	kg/day	= C7/C9	Calculated
12	Steady state *S. americanus* yield	$kg/m^2/y$	= RANDBETWEEN(22,36)/1000	Boyd (1995)
13	Total area of *S. americanus* marshes (low marsh)	ha	917.1	This study
14	Total Fraser River delta *S. americanus* yield	kg/y	= C12*C13*10000	Calculated
15	Proportion of grubbed *S. americanus* biomass consumed	fixed coefficient	1.0	A value of 1 assumes complete utilization
16	Metabolizable caloric value of *S. americanus* yield	kJ	= C14*C9*C15	Calculated
17	Fraser Skagit Snow Goose population	birds	= (((C16/(((C2*C7)+ ((1-C2)*(C6+C5)))*C8)))/47.764)	Calculated using regression: autumn goose-days in Fraser = 47.764*Fraser-Skagit segment Data from Boyd (1995); y-intercept = 0; df = 5; $r^2 = 0.80$

ADDENDA

Last Flight?

My third, and supposed final, flight of 10 November 2005 was in a De Havilland Dash 8 that was to take me home from a journey that began a few hours earlier in a 6-seat Piper Navaho that departed from a snow-covered gravel strip in northern B.C., then continued in a Bombardier CRJ from Prince George to Vancouver (YVR). The westbound departure from YVR's runway 26L would take us over the marsh along the foreshore of Sea Island. It was like so many others I've been on since 1994 when I began studying bird-hazards to aircraft at YVR and helped develop their 24/7 wildlife control program to mitigate those hazards—many of which I had witnessed first-hand. There I was, wondering what critters might be flying around in the flight path this time. For night-time flights such as this, my usual thoughts turn to some poor, unsuspecting barn owl out patrolling the airfield in search of a plump vole. But this time a far more serious hazard was pondered: snow geese that breed in the Russian arctic and winter here by the tens of thousands. By chance, I had just submitted a manuscript for publication earlier in the week, addressing adverse effects of a burgeoning snow goose population on the Fraser Delta. And two days earlier on final approach I had spied a flock of geese loafing in the marsh near the flight path. I had heard recently that the wintering flock this year was bigger than ever.

With plenty of runway lights still below us, we levitated steeply into the darkness. By the time we were over the marsh, we'd reached an altitude that, based on my numerous hours of field-observations from a ground station near the runway's end, led me to believe that we had cleanly escaped the main bird-hazard zone yet again. Still, I peered out the right side at the faintly illuminated propeller hauling us into the blackness.

At some 300+ km/h in the dark there was no chance for more than a glimpse of three or four whitish blurs, accompanied by subtle impact vibrations so transient that I can't remember if they were heard, felt, or both. Snow geese? Gulls? "Shit!" seemed like the right thing to say, so I did as I sat there with a helpless feeling wondering what, if any, damage had been done, and on tenterhooks bracing for more white blurs that, luckily, didn't appear.

As the craft began its usual roll toward Victoria I said to myself, "Okay, maybe I'm making this out to be a bigger deal than it is," thinking that my heightened awareness of bird hazards probably causes me to fret more than I should. Except this time, the turn continued a bit longer so that instead of heading over the Strait of Georgia, we were heading southeast over the lights of Delta. I knew something was amiss. Then the captain announced that we'd hit some birds and that we were going back to YVR for an "inspection". Well, at least the plane sounded okay and I couldn't see any evidence of severe damage like fire or smoke. Touchdown, taxi, stop, shutdown, back home—sort of.

Sitting on the apron and watching an aircraft mechanic inspect the wing, cowling, and what looked to be a bloodstained propeller (I surmised that blood does not show up so clearly on a black background) some questions arose. Can his flashlight look-see really pronounce the plane safe? Should I just grab my gear, walk off this plane and board another? Is it too late to catch a ferry? I sat there knowing that bird-strikes are not that uncommon and that by choice or not, the simple fact that I choose to fly means that I must have some faith in our air industry's standards and its technicians and mechanics. Besides, what could I know of the condition of any other aircraft in the fleet? When the captain announced that the plane was damaged and that we would have to deplane and board another, well, let's just say that I was not put out.

As deftly handled by the gate crew on what was already a very busy evening for regional air-travel out of Gate C38, within an half an hour 37 of the original 50 of us were lining up to board a shorter Dash 8. The others might seek the calming benefit of a pint or two before catching their ride. On the way out of the covered walkway I engaged the ground crewman's humour about this time we should avoid the "shredded tweet"; taking it as a reference to the fact that this mustn't be a particularly unique event if it's got its own pun. Yet I must say that his humour was tempered somewhat by my second-hand knowledge of the deadly havoc a few birds can wreak when they strike the "wrong" parts of a fully loaded, outbound plane.

I'm happy to report the most exciting thing about the fourth of my supposed three plane rides that day was the "free" candy. Home safe (but a little shaken) in time for dinner. My next trip to YVR will be on Thursday. Faith be with me.

Baldwin, Roger A., Allan E. Houston, Michael L. Kennedy, and Pin Shuo Liu. 2006. Predicting Raccoon, *Procyon lotor*, occurrence through the use of microhabitat variables. Canadian Field-Naturalist 120(2): 225-231.

Recent increases in Raccoon (*Procyon lotor*) abundance have been implicated for decreased nesting success of songbirds and transmission of rabies. Understanding the relationship between occurrence and microhabitat factors should be helpful in managing this species, though our current understanding of this relationship is inadequate. Therefore, we conducted a study in western Tennessee during 2000–2002 to determine this association. Occurrence (capture) data were assessed from results of live trapping at 176 and 112 trap sites during winter and summer, respectively, at three sites. A maximum of 26 habitat variables were measured at each trap location; all grids were combined for statistical analyses to account for varying relationships between occurrence and microhabitat factors across different landscapes. Univariate and stepwise logistic-regression analyses were used to assess associations among microhabitat variables and occurrence. Resulting models were validated through the jackknife procedure. Predictive equations were constructed from logistic-regression models to compute capture probabilities. Univariate analyses yielded numerous significant variables with those representing forest characteristics and proximity to water generally the most significant. Strong concordance was observed between winter and summer seasons for most variables though several differed (number of large hardwood snags, ground dens, and plant food species, distance to potential water and roads). Such temporal variability was expected due to seasonal differences in habitat components and biological needs of Raccoons. Variables included in derived models were similar to those scoring highest in univariate analyses; classification rates for models (winter = 72%; summer = 78%) were among the highest recorded for generalist species. By accounting for landscape attributes and replicating across sites, more accurate and useful models were developed. Such models should provide the information required to effectively manage this species.

Key Words: habitat partitioning, logistic regression, mesopredator, microhabitat, *Procyon lotor*, Raccoon, western Tennessee.

Raccoons (*Procyon lotor*) and their associated habitats have been the subject of several biological investigations (see Lotze and Anderson 1979; Kaufmann 1982; Broadfoot et al. 2001; Gehrt 2003). At a landscape level, this medium-sized predator (mesopredator) is thought to be most abundant in aquatic associated habitats (Johnson 1970; Minser and Pelton 1982). However, Raccoons can thrive in an array of habitats although seeming to depend on particular features to reach high and stable populations (Broadfoot et al. 2001; Zeveloff 2002). Several investigators (i.e., Morris 1987; Pedlar et al. 1997; Chamberlain et al. 2002) have noted that knowledge of spatial scale and landscape composition is integral to understanding habitat associations of species, though at present, much of the understanding of the relationship of Raccoons to their habitat is based on assumptions drawn from investigations (e.g., Sanderson 1987; Minser and Pelton 1982; Oehler and Litvaitis 1996) conducted at the landscape level (macrohabitat). The relationship between the occurrence (defined as presence at a location) of Raccoons and microhabitat factors has not been studied at multiple sites collectively and findings of previous investigations (Leberg and Kennedy 1988; Kennedy et al. 1991; Kissell and Kennedy 1992; Pedlar et al. 1997) indicate various associations depending on season and location. Currently the relationship between the occurrence of Raccoons and habitat variables appears to be unclear and in need of additional study (Kissell and Kennedy 1992; Chamberlain et al. 2003), and models allowing for the prediction of occurrence based on microhabitat factors are lacking from the published literature.

Previous studies (Noss et al. 1996; Oehler and Litvaitis 1996; Rogers and Caro 1998) have indicated that due to a combination of factors (e.g., removal of top predators, altered land use, reduced hunting), abundance of mesopredators has increased in recent years. Estes (1996) noted that increased mesopredator populations could influence numerous aspects of ecosystems. For example, high densities can have negative effects on populations of ground-nesting birds (Crabtree and Wolf 1988; Vickery et al. 1992; Schmidt 2003) and, by enhancing the spread of diseases, can impact negatively the health of populations (Carey and McLean 1983; Hill et al. 1993; Schuburt et al. 1998; Rosatte 2000). Predators play an important role in structuring biological communities (Meffe et al. 1997), and an increase in abundance of these species requires strong management

and conservation planning to limit the negative impact of these taxa on ecosystems. However, sound management and conservation plans are difficult to derive without a clear understanding of specific habitat factors critical to target species. At this time, managers of natural resources are faced with increasing populations of Raccoons but limited habitat information on which to make management decisions (see Rosatte 2000 for the consideration of habitat factors in controlling rabies). In particular, models allowing for the prediction of Raccoon occurrence are lacking. For example, certain factors are important components in determining Raccoon occurrence (e.g., den sites and aquatic habitats, Pedlar et al. 1997; Broadfoot et al. 2001; Henner et al. 2004). However, the exact relationship among these components is not known, thereby requiring individuals to make management decisions without the necessary information (i.e., containing rabies outbreaks, Rosatte et al. 2001). Therefore, the purpose of this study was to assess at a microhabitat scale the relationship of occurrence of Raccoons (based on capture frequency) with selected habitat factors from multiple sites representing a mosaic of habitat types. Specifically, the following predictions were assessed: (1) there is an association between occurrence (based on capture) and selected (individual) habitat variables; and (2) selected habitat variables can be used to construct models predictive of species occurrence.

Study Area

This study was conducted in temperate deciduous forest in western Tennessee characterized by a fragmented landscape consisting of various levels of forest, early successional and agricultural fields, residential buildings, and road systems at three sites. Site 1 was located at the Edward J. Meeman Biological Station (Meeman), which was located approximately 20 km north of Memphis, Tennessee (35°33'N, 90°09'W). This location was comprised primarily of hardwood forests with old-field and Kudzu (*Pueraria lobata*) habitats interspersed throughout. Old-fields were dominated by goldenrod (*Solidago* spp.), fescue (*Festuca* spp.) and Switch Grass (*Panicum virgatum*). Topography of the site was characterized by numerous drainages that resulted in a gently rolling terrain throughout the area. Upland and bottomland forests included various oaks (*Quercus* spp.), hickories (*Carya* spp.), and maples (*Acer* spp.) as well as Tulip Poplar (*Liriodendron tulipifera*) and Sweet Gum (*Liquidambar styraciflua*; Maris 1998). Several small ponds and intermittent streams occurred throughout the site.

Sites 2–3 were located at the Ames Plantation (Ames; 35°06'N, 89°12'W), which was a 7462 ha farm located northwest of Grand Junction in Fayette and Hardeman counties, and was operated by The Hobart Ames Foundation in cooperation with the University of Tennessee. Ames was located approximately 79 km southeast of Meeman. Site 2 was located adjacent to the North Fork of the Wolf River. It was comprised primarily of agricultural fields and bottomland hardwood forest with some upland forest present. Site 3 was composed of upland and bottomland forest, cropland, and old-field habitats. In general, agricultural crops included Soybeans (*Glycine max*), Corn (*Zea mays*), and cotton (*Gossypium* spp.). Typical upland tree species were Loblolly Pine (*Pinus taeda*), oaks, and hickories; typical bottomland species included oaks, maples, Cottonwood (*Populus deltoides*), and Sweet Gum (Gabor 1993). Old-field habitats included native warm season grasses and were similar to those at Meeman. Topography of upland forest sites was characterized by gently rolling slopes, whereas bottomland forest, old-field, and agricultural areas constituted a flatter topography. Ponds and intermittent streams were numerous, and drainages were interspersed throughout all of these sites.

Methods

Trapping grids were established at each site. Site 1 followed a 5 × 10 trap configuration with traps located approximately 150 m apart. Sites 2–3 followed an 8 × 8 trap configuration with traps located approximately 230 m apart though two trap locations were excluded from analysis for site 2 as habitat factors were not measured. Difference in trap configuration for site 1 was due to the limited size of the area. Collectively, the three sites represented most habitat types occurring in western Tennessee.

The association of microhabitat variables and occurrence of Raccoons was assessed during two periods that coincided with times when leaves were present or absent (winter and summer, respectively) on most woody and herbaceous vegetation (Kolowski and Woolf 2002). During winter, sites were operated on selected nights from 3 November–7 April, 2000–2002; summer trapping included only sites 1–2 and were operated on selected nights from 7 May–12 October, 2001–2002. An approximate total of 2000 trap nights (one trap night = one trap set for one night) were observed for each site during both seasons.

Raccoon-size Tomahawk (Number 108; Tomahawk Live Trap Co., Tomahawk, Wisconsin, USA) and Havahart (Woodstream Corporation, Lititz, Pennsylvania, USA) live traps were used. Traps were baited with canned cat food in winter and a combination of cat food, dog food, and doughnuts in summer. Initially captured individuals were anesthetized with a mixture of ketamine hydrochloride (Ketaset; Bristol Laboratories, Syracuse, New York, USA) and acepromazine maleate (PromAce; Ayerst Laboratories, New York, New York, USA) at a 10:1 ratio with 0.1 cc of ketamine hydrochloride used per estimated kg of live weight (Bigler and Hoff 1974). Raccoons were tagged in both

ears with Number 3 Monel (National Band and Tag Company; Newport, Kentucky, USA) ear tags to determine recaptures.

For the winter season, 19 habitat variables were measured to determine the influence of habitat at the micro-scale on raccoon occurrence. "Slope" represented the average percentage slope for a 32 m radius around the trap site as measured by a clinometer. "Total basal area" [≥5 cm diameter at breast height (dbh)], "basal area of small trees" (5–35 cm dbh) and "basal area of large trees" (>35 cm dbh) represented the amount of area (m^2) covered by trees per hectare and were determined through use of a prism sweep (10 basal area factor prism) conducted at the trap site and at two additional sites 11.4 m in two random cardinal directions. Heights were recorded for each tree measured during the basal area estimation using a haga altimeter (Forestry Suppliers, Inc., Jackson, Mississippi, USA) with the mean recorded as "average height". "Number of fallen logs" (≥10 cm in diameter) "number of total snags" (≥10 cm dbh), "number of small hardwood snags" (10–35 cm dbh), "number of large hardwood snags" (>35 cm dbh), "number of pine snags" (≥10 cm dbh), "number of ground dens", "number of tree dens", and "number of total dens" were counted within a 32 m radius of trap site. An opening of ≥5 cm in diameter was required to be considered a potential den. The "number of plant food species" represented the number of plant species present within a 32 m radius of the trap site that could be utilized as food sources. The "number of stems" 1–5 cm in diameter was counted for a 3.2 m radius around the trap site. The procedure was repeated in two random cardinal directions 11.4 m from the trap site and the average used. "Distance to potential water" represented the nearest distance to a water source that held water ≥30 days a year. "Distance to permanent water" was the minimum distance to a water source that held water ≥11 months a year. "Distance to road" was measured to the nearest road or man-made vehicular trail, while "distance to open area" represented the nearest distance to a non-forested patch. All distance measurements were in meters and were measured using digital orthophoto quarter-quadrangles georeferenced in ArcView software.

Seven additional variables were assessed during the summer season yielding a total of 26. "Depth of leaf litter" was averaged from 10 random measurements taken within a 32 m radius around the trap site. "Vertical cover" was assessed through the use of a 2 m × 0.2 m cover board checkered with 0.1 × 0.1 m black and white squares. The percentage of board uncovered was recorded at the trap site in all four cardinal directions. The percentage of squares uncovered on a spherical densiometer (Forestry Suppliers, Inc., Jackson, Mississippi, USA) was recorded to determine "canopy cover". Readings were taken in all 4 cardinal directions at the trap site. "Grass cover", "woody cover", "forb cover", and "bare soil cover" were visually estimated for a 3.2 m radius around the trap site. All procedures for measuring summer variables (except "depth of leaf litter") were repeated in two random cardinal directions 11.4 m from trap site and the average used.

Because the purpose of this investigation was to assess at a microhabitat scale the relationship of occurrence of Raccoons from multiple sites, statistical analyses were conducted only on data from all sites combined for both winter and summer seasons. A natural log transformation was applied to all continuous variables; percentage variables were arcsine transformed to approximate a normal distribution (Zar 1999). Univariate logistic regression was used to assess associations between single habitat variables and Raccoon occurrence with a non-adjusted $\alpha = 0.05$ to indicate significance following suggestions by Moran (2003).

In stepwise logistic-regression analyses, an $\alpha = 0.15$ was used as a minimum threshold for inclusion into the regression function to reduce the data set (Hosmer and Lemeshow 2000). Multicollinearity effects between two significant variables were addressed by assessing correlations among habitat variables. If two significant variables were correlated at $r \geq 0.70$, only the more significant variable of the pair was included in further analyses to reduce redundant variables (Agresti 1996).

Variables remaining after univariate logistic regression were included in a backward stepwise logistic-regression function and were removed from the model at $P > 0.15$. Subsequent models often contained a large number of variables. Therefore, for practicality and management purposes, these models were reduced further by forcing exclusion of variables with lowest t ratios resulting in a minimum variable model. The t ratio represents the ratio of each regression coefficient to its standard error. Relative importance of variables included in the final models was ascertained through t ratios, with maximal t ratios reflecting the best variable to predict occurrence (Hacker and Coblentz 1993; Hosmer and Lemeshow 2000; Kolowski and Woolf 2002).

Percentage correct classification of trap sites was determined using logistic regression models. Accuracy of these models was determined using the jackknife procedure as a pseudo-validation technique (Morrison 1976; Kolowski and Woolf 2002). This procedure tested percentage correct classification by removing one trap site at a time and then classified that site based on the model built from all other sites combined, resulting in a less-biased percentage classification (Hacker and Coblentz 1993; Kolowski and Woolf 2002). All statistical procedures were conducted using SYSTAT 10.0 (SPSS 2000).

Results

Trapping resulted in 209 total captures of 112 individual Raccoons obtained from 176 trap sites in winter

TABLE 1. Resulting *t* ratios and *P* values from univariate logistic regression of captures of Raccoons (*Procyon lotor*) compared to habitat variables at three sites during winter and two sites during summer 2000–2002 in western Tennessee. All variables are considered significant at $P < 0.05$. Basal area measurements are per ha. Height and distance measurements are in m. See text for explanation of variables.

	Winter (n = 12454)		Summer (n = 8406)

[a] Variable included in stepwise logistic-regression function.

(site 1 = 100 total captures of 49 individuals; site 2 = 40 total captures of 26 individuals; site 3 = 69 total captures of 37 individuals) and 173 total captures of 117 individuals from 112 trap sites in summer (site 1 = 93 total captures of 52 individuals; site 2 = 80 total captures of 65 individuals).

Winter.—Sixteen habitat variables were significant statistically when compared to Raccoon occurrence using univariate logistic regression; greatest positive associations occurred for basal area of large trees and total basal area, whereas the strongest negative association was for distance to potential water (Table 1). The only habitat variable not closely related to Raccoon occurrence was distance to road. Through stepwise procedures and model construction, six variables (four positive, basal area of large trees, number of plant food species, number of tree dens, basal area of small trees; two negative, distance to potential water, number of total dens) were selected (Table 2). Percentage of trap sites correctly classified was 72%.

Summer.—Thirteen habitat variables were significantly associated to Raccoon occurrence based on univariate logistic regression; strongest positive associations were for total basal area, basal area of large trees, basal area of small trees, and bare soil, whereas distance to permanent water and canopy cover had the strongest negative associations (Table 1). In general, variables associated to basal area, height of stand, number of logs, den sites, canopy cover, number of stems, bare soil, and distances to permanent water, roads, and open areas were associated to occurrence; variables not associated to occurrence included snags, leaf litter, food species, vertical density, vegetative ground cover, and potential water sources. Three significant variables (two positive, total basal area, distance to road; one negative, distance to permanent water) were selected through subsequent stepwise procedures and model construction resulting in the correct classification of 78% of trap sites (Table 2).

Discussion

Univariate analyses yielded numerous significant variables indicating those selected for the current investigation influenced Raccoon occurrence. These variables were similar to those correlated in previous investigations (e.g., association with forest characteristics,

TABLE 2. Regression coefficients, *t* ratios, and *P* values (*P*) for Raccoons (*Procyon lotor*) derived from logistic-regression functions, as well as percentage correct classifications using the jackknife procedure. Data included in analyses were as follows: winter = three sites totaling 12454 trap nights; summer = two sites totaling 8406 trap nights. See text for explanation of variables and sampling locations.

		Logistic regression			Jackknife classification

[a] Percentage correct classification of sites with no captures.
[b] Percentage correct classification of sites with captures.
[c] Percentage correct classification of all sites combined.

Leberg and Kennedy 1988; Kennedy et al. 1991; Pedlar et al. 1997; Dijak and Thompson 2000; association with water sources, Leberg and Kennedy 1988; Dijak and Thompson 2000) and suggest that a strong component of forested areas with large trees and close proximity to water sources are important factors in predicting Raccoon occurrence. Additional variables significant in the present investigation were not significant in other studies (e.g., average height, slope, and distance to roads — Leberg and Kennedy 1988; Kissell and Kennedy 1992). This lack of concordance may be attributed to differences in landscape composition and a lack of replication (Maurer 1986; Temple and Wilcox 1986; Oehler and Litvaitis 1996). Baldwin (2003) found similar results when addressing individual sites for Virginia Opossums (*Didelphis virginiana*) in western Tennessee. However, by assessing multiple sites, noticeable trends were observed. The lack of concordance for individual sites was attributed to differing landscape compositions. By assessing multiple sites of similar landscape composition, the difference in significant habitat factors dissipated. Similar results were observed for Striped Skunks (*Mephitis mephitis* — Baldwin et al. 2004) and suggest that landscape composition is an important factor when constructing models predictive of occurrence (Temple and Wilcox 1986; Dijak and Thompson 2000).

Differential use of habitat by Raccoons across seasons has been documented (e.g., Lotze and Anderson 1979; Kaufmann 1982; Chamberlain et al. 2002), although quantitative assessments of these shifts among seasons have received little study. Nevertheless, concordance of significant variables across seasons was generally high although a few exceptions were noted. For example, large hardwood snags and ground dens were important factors during winter but were non-significant during summer. Both variables provide thermal shelter for Raccoons during winter (Stains 1961; Sanderson 1987) but may be less important during warmer seasons. Likewise, number of plant food species and distance to roads were significant factors during winter but not in summer. The non-significance of these variables may be related to the abundance of food and the lack of hunter use of roads during summer. This non-use of roads as travel corridors may have resulted in increased use of stream banks during winter (Hilty and Merenlender 2004), thus yielding different results between seasons for distance to potential water. Ultimately, temporal variability should be expected due to seasonality in variables measured as well as in the biological needs of Raccoons and should be considered when modeling Raccoon occurrence.

Most previous investigations have attempted to determine those factors most important in influencing Raccoon occurrence at the micro-scale but did not include modeling techniques in their analyses (Leberg and Kennedy 1988; Kennedy et al. 1991; Kissell and Kennedy 1992; but see Pedlar et al. 1997 for different modeling strategy). Such modeling strategies allow for the prediction of heavy-use areas by Raccoons and are particularly useful to managers of natural resources. Therefore, such procedures were incorporated into the current investigation and yielded models that generally included the strongest variables from univariate analyses (i.e., forest and water characteristics). Resulting models maintained high classification rates while allowing managers to focus only on those variables most important for predicting Raccoon occurrence. Such techniques have yielded slightly higher classification rates for habitat specialists [Fisher (*Martes pennanti*) = 79% — Carroll et al. 1999; Iberian Lynx (*Lynx*

pardinus) = 83% — Palma et al. 1999] likely due to their need for more specific habitat components. Nonetheless, classification rates observed in the current study are generally higher than those reported for other habitat generalists [Bobcat (*Lynx rufus*) = 59–70% — Kolowski and Woolf 2002; Striped Skunk = 56–75% — Baldwin et al. 2004]. Therefore, models that utilize replicated sites and account for differences in landscape composition could serve as a blueprint for future investigations involving habitat generalists ultimately resulting in models more useful for wildlife managers. Unfortunately, construction of such models can be expensive. Care must be taken to develop an appropriate sampling strategy to maximize results.

Acknowledgments

Partial funding for this project was provided by the Tennessee Wildlife Resources Agency, the Ames Plantation, and The University of Memphis. Thanks are extended to S. B. Franklin for critical review of the manuscript, and to M. Biernacki, S. B. Franklin, and T. A. Wasklevicz for assistance with statistical analysis and GIS application. Special thanks go to B. D. Carver, J. R. Hisey, J. B. Jennings, S. J. Mahady, and numerous students from The University of Memphis, as well as several individuals from the University of Tennessee and the Ames Plantation for their assistance in data collection.

Notes

Scoter, *Melanitta* spp., Migrations Interrupted by Confederation Bridge: An Update

KATHERINE BUNKER-POPMA

40 Weldon Street, Sackville, New Brunswick E4L 4N4 Canada

Bunker-Popma, Katherine. 2006. Scoter, *Melanitta* spp., migrations Interrupted by Confederation Bridge: An update. Canadian Field-Naturalist 120(2): 232-233.

Continued monitoring over 10 years of scoter migrations through Northumberland Strait confirmed that these birds continue to perceive the Confederation Bridge (completed in 1997) as an obstacle. Such problems – and alternatives not causing them – need serious consideration when "strait crossings" are contemplated elsewhere.

Key Words: Scoters, *Melanitta* spp., migrations, Northumberland Strait, bridge, New Brunswick.

While the Confederation Bridge (46°15'N, 63°40'W) linking Prince Edward Island to New Brunswick was being completed in 1997, Hicklin and Bunker-Popma (2001) examined the possible influence of the bridge upon migration by marine birds. They concluded that migrating scoters (*Melanitta* spp., seaducks) were unwilling to fly under the (40 metre high) bridge and often reluctant to fly over it.

Earlier information, recently supported by several studies (e.g. Wilson et al. 2003*), suggested that, in recent years at least, most migrating scoters passing through the Maritime Provinces in spring cross the Chignecto Isthmus 40-50 km. further west and do not approach the Confederation Bridge. Much less is known about their fall migrations.

TABLE 1. Ten years of scoter movement at Confederation Bridge, New Brunswick/Prince Edward Island. Spring (S) and fall (F) totals shown separately for each year.

Year		Observation time (hr)	Scoters seen to approach bridge	Scoters seen to pass over bridge* (%)	
1997	S	54	731	243	(33)
	F	102	876	338	(39)
1998	S	15	70	29	(41)
	F	49	923	388	(42)
1999	S	4	16	0	
	F	78	1495	881	(59)
2000	S	35	389	67	(17)

Grand Totals		826	14961	7377	(49)

* No scoters were seen to pass under the bridge

I monitored seaduck migrations at Confederation Bridge each year since 1997, using procedures of our original study (Hicklin and Bunker-Popma 2001) to see if these birds habituated to the perceived obstacle. Results of these observations, summarized in Table 1, suggest that the majority of scoters still, after 10 years, have not learned a simple, general, way of passing the bridge.

Nearly half of those seen (34% in spring, 53% in fall) circled upwards and passed extremely high over the bridge without landing. Others landed on the water, and remained there, often for hours. Still others followed the bridge towards the opposite shore, and sometimes were lost to sight while still flying. As my observations do not suggest that birds in the two latter categories stay near the bridge indefinitely, presumably they continue their migrations later, but timing of their departures and the routes followed remain unknown.

Given the small fraction of regional scoter populations that approach it, this bridge cannot be considered a major obstacle to their migrations, at a flyway level. Nevertheless, the continuing problem posed to the birds that encounter this bridge needs to be borne in mind whenever and wherever bridges are proposed in locations traversed by major portions of migratory species populations.

Acknowledgments

An Observation of the Spring 2006 Migration of Black Scoter *Melanitta nigra*, in Northumberland Strait, Interrupted by the Confederation Bridge, New Brunswick – Prince Edward Island

COLIN MACKINNON and ANDREW KENNEDY

Canadian Wildlife Service, Atlantic Region, P. O. Box 6227, Sackville, New Brunswick E4L 1G6 Canada

MacKinnon, Colin, and Andrew Kennedy 2006. An observation of the spring 2006 migration of Black Scoter *Melanitta nigra*, in Northumberland Strait, interrupted by the Confederation Bridge, New Brunswick – Prince Edward Island. Canadian Field-Naturalist 120(2): 233-234.

An observation from the bridge of a flock of Black Scoters suggests that, nine years after construction, the 12.9 km Confederation Bridge may still be a partial barrier to bird migration. Only 3 of 18 scoters (16.7%) crossed over the structure during the observation period.

Key Words: Black Scoter, *Melanitta nigra*, seaducks, migration, Confederation Bridge, Northumberland Strait, New Brunswick, Prince Edward Island, Cape Jourimain National Wildlife Area.

Construction of the Confederation Bridge began in 1995 and was completed in 1997. This 12.9 km concrete structure spans the Northumberland Strait at its narrowest point between the Cape Jourimain National Wildlife Area, New Brunswick, and Borden, Prince Edward Island. As part of collecting pre-construction baseline data in 1990, MacKinnon et al. (1991) monitored seabird and seaduck movement through the Northumberland Strait. Twenty-two hours of surveys, during spring and fall, produced 5214 observations on 25 species. Of these, 2041 (39.1%) were seaducks, 1400 (26.9%) were three species of scoters and 641 (12.3%) were Common Eider, *Somateria mollisima* (MacKinnon et al. 1991).

During the early 1990s, concerns were expressed over possible effects the Confederation Bridge may have on seabird migration. The closest comparable existing structure was the Canso Causeway, connecting Cape Breton Island with mainland Nova Scotia. Erskine and Smith (1986) reported that, although the causeway was a comparatively low and short structure, Common Eider were believed to have treated the structure as a barrier to flight. A flock of eiders flew parallel to the causeway, gained altitude, and eventually crossed over. The question was, would seaducks do the same with the Confederation Bridge?

In 1997, Hicklin and Bunker-Popma (2001) conducted surveys at Confederation Bridge during spring

migration, similar to those reported by MacKinnon et al. (1991). The Confederation Bridge was then operational, and their observations suggested that it formed a partial barrier to scoter migration. Of 3986 and 1441 scoters observed by them during respective spring and fall migration, only 12.8% of scoters crossed over the bridge during the spring and slightly more, 21.9%, in the fall. Bunker-Popma (2006) subsequently reported additional years of observation.

The Confederation Bridge utilizes a multi-span concrete box girder structure and is composed of three main components: the approaches (east and west), a 40 m-high deck and 60 m-high ship-navigation span. The east approach is 0.6 km over 7 piers and the west approach is 1.3 km over 14 piers. The main bridge is 11.0 km (44 piers) in length. In the middle of the bridge is a 2.50 km navigation section. The typical span, between piers, is 250 m.

The Confederation Bridge has been in operation for nine years. During the morning of 13 April 2006, we observed the behaviour of a flock of Black Scoters, *Melanitta nigra,* during their northward migration (46°13'N, 63°44'W). This observation proved more interesting as the authors were travelling across the bridge, by vehicle, at the time and were able to track the flock's activities over most of the crossing. At the time of observation, visibility was excellent, no clouds, +6°C and wind light SSW.

Shortly after we entered the Confederation Bridge from Borden, Prince Edward Island, at 08:10, a flock of 18 Black Scoters was observed flying parallel with and approximately 100 m south of the Bridge at a height of approximately 40 m above the water. The flock was observed to rise and approach the bridge deck on three occasions. On two occasions, the flock approached the deck and then veered back to its original flight path, parallel with the Bridge. On the third occasion, the flock gained altitude and, similar to the previous occasions, aborted its attempted flight over the bridge after coming within approximately 50 m of the structure. However, this time the flock completed a clockwise circle, towards the bridge, in order to regain their original flight path. At the instant in which the flock began this circle, three birds broke from the main group and promptly crossed over the Bridge, behind our vehicle, at a height of approximately 10 m above the bridge deck. This crossing occurred approximately 4.5 km from the Prince Edward Island side of the bridge. The velocity of the flock was constant with our driving speeds of about 80 km/h, until it could no longer be viewed in the vicinity of the navigation channel. While rising over the navigational channel, the scoters remained out of sight below us. We maintained a constant speed of 80 km/hr and the flock was immediately re-sighted once we descended from the elevated navigation span. Upon re-locating the flock, we noted that the group had decreased in size, while out of sight, from 15 to 8 birds. We did not observe any scoters coming into view on the north side of the Bridge and assume the missing seven birds did not cross the structure. The remaining eight birds eventually landed in the water approximately 100 m south of the bridge and 500 m from the New Brunswick coastline (46°10'N, 63°49'W). Observations ceased at 08:25. It is noteworthy that the Confederation Bridge is built in a general "S" curve, thus the flight of the scoter flock was following the contours of the bridge and not a straight line.

This observation demonstrates that nine years after the Confederation Bridge was built, some seaducks, such as Black Scoters, still may perceive the structure as a partial barrier to their northward migration through the Northumberland Strait.

Acknowledgments

We thank P. Hicklin, K. Davidson and A. J. Erskine for helpful reviews of the manuscript.

First Record of a River Otter, *Lontra canadensis*, Captured on the Northeastern Coast of Alaska

SHAWN P. HASKELL[1]

[1]LGL Alaska Research Associates, Inc., 1101 E 76th Avenue, Suite B, Anchorage, Alaska 99518 USA, e-mail: shawn.haskell@ttu.edu

Haskell, Shawn P. 2006. First record of a River Otter, *Lutra canadensis*, captured on the northeastern coast of Alaska. Canadian Field-Naturalist 120(2): 235-236.

A River Otter (*Lontra canadensis*) was captured on the Beaufort Sea coast of northeastern Alaska during a coastal fish study in late July 2001. The otter was dead upon retrieval and of adult size. River Otter distribution is not known to extend north of Alaska's Brooks Range. This occurrence may have represented a one-time spring dispersal event. However, fluviomorphological features of some river systems may provide suitable habitat for an overwintering otter in this region of Alaska's North Slope.

Key Words: River Otter, Beaufort Sea, *Lutra canadensis*, fyke net, distribution, Alaska.

In late July 2001, a River Otter (*Lontra canadensis*) of adult size was retrieved from a shoreline fyke net in Lions Bay, a barrier island lagoon system on the Beaufort Sea coast of northeastern Alaska. The live-capture fishing net was located at 70°10.024'N, 146°12.557'W, approximately 82 km east of Prudhoe Bay and 11 km west of the Canning River; the nearest non-industrial areas of human habitation are Barter Island, 100 km to the east, and the Colville River delta, 170 km to the west. A westerly wind event had caused coastal water levels to rise, completely submerging the trap-end of the net in about 1.5 m of water, drowning the otter. Physical samples or measures were not taken of the specimen. The animal was discarded to the water at the capture site. About two weeks after the capture, the author retrieved the carcass for brief examination. Marine arthropods of the family Mysidae had entered all openings in the otter's body, expediting decomposition.

River Otter distribution is commonly noted as extending far north up the Mackenzie River drainage of northwestern Canada but then falling south of the Alaskan Brooks Range to the west (Rue 1981; Whitaker 1996; Forsyth 1999; Wilson and Ruff 1999). Bee and Hall (1956) reported a River Otter sighting in the central Brooks Range at Kanayut Lake and tracks observed near the Beaufort Sea coast at the Kuparuk River. Manville and Young (1965) also displayed a point location near the mouth of the Kuparuk River, but given survey methods, that point may stem from the same observation of tracks documented by Bee and Hall (1956). A commercial winter fishery operated in the Colville River Delta since the early 1950s has never captured a River Otter (James Helmericks, homesteader and naturalist, personal communication). There are only two state sealing records for River Otters in Alaska's North Slope region; one was caught near Wainwright in northwestern Alaska in 1990 and the other near Anaktuvuk Pass in the central Brooks Range in 1985 (Geoff Carroll, Alaska Department of Fish and Game Area Biologist, personal communication). Biologists have reported seeing small numbers (i.e., one or two) and tracks of otters north of Anaktuvuk Pass but south of the Arctic Coastal Plain on the Anaktuvuk and Chandler rivers, both tributaries to the north-flowing Colville River, where freshwater upwellings provide open water throughout winter and habitat for fishes such as Arctic char (*Salvelinus alpinus*; Geoff Carroll, Alaska Department of Fish and Game Area Biologist, personal communication).

It is unknown whether the 2001 otter capture in Lions Bay signified an anomalous extralimital occurrence or a case of regular periodic use by otters of this area seldom occupied by humans. Leffingwell (1919) noted that larger rivers in the region supported populations of fish year-round. Relatively small catches of juvenile amphidromous fishes during the summers of 1999 and 2001 in Lions Bay indicated that these fish, and likely some adults of the same species, did overwinter in the area (Griffiths et al. 2002*). Craig and McCart (1974*) identified groundwater springs in the nearby Kavik River and Canning River drainage, as well as a field of *aufeis* in the Canning River Delta, that supported overwintering fish. Some of these areas could potentially provide suitable habitat for an overwintering otter on Alaska's North Slope.

Acknowledgments

This capture occurred during the daily operation of a remote coastal fish study operated by LGL Alaska Research Associates, Inc. The study was funded by the Exxon Owners Group of Point Thomson, administered and reviewed by the Environmental Studies Group of BP Exploration (Alaska) Inc.

Blinn, Brenda M., Vicky Violette, and Antony W. Diamond. 2006. Osprey, *Pandion haliaetus*, depredates Common Eider, *Somateria mollissima*, duckling. Canadian Field-Naturalist 120(2): 236-237.

To our knowledge, we present the first published account of a successful attack on a Common Eider (*Somateria mollissima*) duckling by an Osprey. Ospreys were sighted periodically during 940 hours of Common Eider observations in June-August, 2001 on Grand Manan Island, New Brunswick. One duckling (<1 week old) was observed depredated by an Osprey. Vulnerability of ducklings to predation may promote such opportunistic behaviour. The rarity of observations of such incidents suggests depredation on ducklings by Osprey is uncommon.

Key Words: Common Eider, *Somateria mollissima*, Osprey, *Pandion haliaetus*, predation, Grand Manan Island, New Brunswick.

The diet of Ospreys (*Pandion haliaetus*) consists almost exclusively of live fish (Poole et al. 2002). Coastal populations may switch prey species depending on the pattern and timing of fish migration (Greene et al. 1983). Ospreys are known to feed occasionally on rodents, birds, reptiles, amphibians, and invertebrates (see Wiley and Lohrer 1973 for literature review). Birds reported include grebes, gulls, ducks, including a 2-week old Wood Duck (*Aix sponsa*; Wiley and Lohrer 1973), and passerines (Chubbs and Trimper 1998).

From 7 June to 3 August 2001, a study of Common Eiders (*Somateria mollissima*) was conducted on Grand Manan Island located 35 km from the New Brunswick south shore. It is the largest (25 km long, 11 km wide) of 17 other islands in the archipelago. A total of 940 hours of observations were made at eight 1 km^2 sites, typically between 06:00 and 21:00 h. Duckling numbers and ages were recorded at 20-minute intervals using scan sampling (Altman 1974). Predatory attacks were recorded as they occurred. Eider broods occupied the intertidal zone which was covered with brown fucoid algae (*Ascophyllum nodosum* and *Fucus vesiculosus*) with some rock, sand or mud. A mixed forest of Balsam Fir (*Abies balsama*), spruce (*Picea* sp.) and alder (*Alnus* sp.), as well as shrubs (*Rubus* sp.) and various grasses (Graminae) were usually present within 10-50 m of the high tideline. A vertical tidal range of up to 8.4 m can be expected in this area. Approximately 3370 Common Eider pairs (Ronconi and Wong 2002) and 15 other Anatidae species breed in the archipelago (Dalzell 1991).

On 4 July 2001, an Osprey of unknown breeding status captured and carried off a 0-7 day-old eider duckling approximately 100 m offshore. The researcher (V. V.) was situated near the waterfowl sanctuary of Castalia Marsh (44°42'N, 66°48'W). Just prior to the attack, an eider crèche of 25 adult females and 62 ducklings was observed in the area dabbling for invertebrates. Duckling ages and counts (number) in this group were 0-7 days old (18), 8-13 days old (38), and 14-21 days old (6). At 20:00, the crèche stopped foraging and became alert when an Osprey flew nearby before leav-

ing the site. It returned at 20:03, swooped down, took an eider duckling without any defensive behaviour by the hens, and flew out of sight. The presence of the duckling in the raptor's talons was verified using a Bushnell *Spacemaster* 45-60 × 200 spotting scope. Ospreys were not observed at Castalia for the remainder of the evening. Ospreys were recorded at Castalia and at five other sites during visits both before and after the attack. Only lone Ospreys were seen at any given time, and no nests were present within any of the study sites. Bald Eagles (*Haliaeetus leucocephalus*) also took three ducklings at Castalia and two ducklings at another site approximately 10 km away.

One of the reasons suggested to explain Ospreys taking non-fish prey is reduced visibility caused by turbid water (Chubbs and Trimper 1998). Machmer and Ydenberg (1990) found that capture rate by Ospreys decreased greatly when winds were above 25.2 km/h. On the evening of the attack, moderate winds (~13 km/h), medium-sized waves and clear skies probably did not contribute to poor fishing conditions, although incoming tide and floating algae could have made fish less detectable.

Ospreys may take easily-captured (usually weak or captive) birds when available (Dement'ev and Gladkov 1951). Eider ducklings <3 weeks old have poorly developed diving skills (Hamilton 2001). This makes them vulnerable to predation, especially in the first 10 days of life, with reported mortalities exceeding 90% from gull attacks (Mawhinney and Diamond 1999). Because Ospreys cannot dive deeper than one meter into water (Prevost 1982), they forage in shallow-water environments (Poole et al. 2002). Shallow-water areas are often near brood-rearing habitat of eiders (McAloney 1973).

In spite of many hours of observation of eider crèches in waters surrounding Grand Manan Island, we observed only one instance of duckling depredation by an Osprey. Ducklings less than one week old, which are vulnerable to predation, were observed during five out of eight observation periods (63%) and during 32 out of 309 scans (10%) at Castalia. Therefore, it seems unlikely that this Osprey was a "specialist"; i.e., fed more frequently on ducklings than the average rate for the species. Predation on eider ducklings by Ospreys is evidently a rare event everywhere.

Acknowledgments

Financial, logistical and collaborative support that made this observation possible was provided by the Atlantic Cooperative Wildlife Ecology Research Network (ACWERN) at the University of New Brunswick, the New Brunswick Wildlife Trust Fund, Acadian Seaplants Ltd. and the New Brunswick Department of Natural Resources and Energy. Our sincere gratitude goes to Greg McGuire for his assistance in the field. André Breton provided valuable comments on earlier versions of the manuscript. This is ACWERN Publication Number UNB-59.

Extension de l'aire de distribution de l'Umbre de vase, *Umbra limi*, dans le nord-est du Québec

JEAN-FRANÇOIS DESROCHES[1]

[1] Cégep de Sherbrooke, Département des Techniques de bioécologie, 475 rue du Cégep, Sherbrooke, Québec J1E 4K1 Canada; e-mail: Jean-Francois.Desroches@cegepsherbrooke.qc.ca

Desroches, Jean-François. 2006. Extension de l'aire de distribution de l'Umbre de vase, *Umbra limi*, dans le nord-est du Québec. Canadian Field-Naturalist 120(2): 238-239.

Le 26 juillet 2005, plusieurs Umbres de vase (*Umbra limi*) ont été capturés au secteur Les Buissons de Pointe-aux-Outardes, sur la Côte-Nord au Québec. Ces mentions élargissent l'aire de distribution de ce poisson de 300 km vers le nord-est.

On 26 July 2005, we caught many Central Mudminnows (*Umbra limi*) at the Les Buissons sector of Pointe-aux-Outardes, on the Côte-Nord region of Québec. These records extend the known distribution of this fish 300 km to the northeast.

Mots-Clés: Umbre de vase, Mudminnow, *Umbra limi*, distribution, aire de distribution, Québec

L'Umbre de vase (*Umbra limi*) se retrouve dans le centre de l'Amérique du Nord, du centre-sud des États-Unis jusqu'au sud du Canada, vers le nord (Page et Burr 1991). Au Canada, il est réparti d'ouest en est depuis l'Alberta jusqu'au Québec (Scott et Crossman 1974). Au Québec, l'espèce est confinée au sud-ouest de la province, se rendant à l'est jusque dans la région de la ville de Québec selon les données actuellement disponibles (Scott et Crossman 1974; Bergeron et Brousseau 1981; Bernatchez et Giroux 2000).

En juillet 2005, dans le but de capturer des amphibiens aquatiques, deux nasses à ménés ont été placées dans un étang à castors situé dans le secteur Les Buissons de Pointe-aux-Outardes (49°7'47"N; 68°21'36"O). Les nasses ont été relevées le 26 juillet 2005. Dans la première nasse, il n'y avait aucune capture, mais quelques Umbres de vase ont été capturés en fouillant dans l'eau avec une épuisette. Neuf spécimens, soit quatre jeunes (longueur totale 27,0-30,7 mm) et cinq adultes (longueur totale 54,5-62,7 mm) ont été gardés et sont conservés dans la collection de poissons du Musée canadien de la nature (CMNFI 2005-0032). Dans la seconde nasse se trouvaient une jeune Anguille d'Amérique (*Anguilla rostrata*) vivante et les restes de deux Umbres de vase, probablement dévorés partiellement ou régurgités par l'anguille. Des fouilles effectuées avec une épuisette ailleurs dans l'étang, la même journée, ont permis la capture de quelques autres Umbres de vase et de têtards de grenouilles.

Cet étang à castors est relié à un lac plus gros, le lac Lagacé, qui a une superficie d'environ 6 ha (850 m × 85 m). Le contour de l'étang est irrégulier, l'eau est teintée de brun, et on y retrouve quelques arbres morts. Il présente certains méandres vaseux où l'on retrouve un peu de végétation aquatique submergée. La forêt bordant l'étang est mixte et composée notamment d'épinettes (*Picea* sp.), de Sapin baumier (*Abies balsamea*) et de Bouleau blanc (*Betula papyrifera*). Des aulnes (*Alnus* sp.) bordent l'étang.

L'Umbre de vase est une espèce tolérante reconnue pour vivre dans des eaux chaudes et riches en végétation, généralement peu oxygénées (Scott et Crossman 1974). Dans le sud-ouest du Québec, on le trouve dans les baies riches en végétation des lacs et rivières lentes, dans les étangs à castors et les étangs de tourbières, et dans les fossés (observation personnelle). Les plans d'eau retrouvés sur la Côte-Nord sont en général des lacs clairs typiques à l'Omble de fontaine (*Salvelinus fontinalis*), habitat peu propice à l'Umbre de vase. On y retrouve également des étangs à castors et des tourbières, lesquels sont plus favorables à l'espèce. L'Umbre de vase pourrait donc se retrouver ailleurs sur la Côte-Nord.

La découverte de l'Umbre de vase sur la Côte-Nord au Québec, à 300 km au nord-est de sa distribution actuellement connue, revêt un intérêt particulier. Il apparaît probable que ce poisson soit plus répandu qu'on le croyait au Québec et qu'il ait été sous-inventorié. Il s'agit d'une petite espèce ne présentant aucun intérêt pour la pêche sportive ou commerciale et vivant le plus souvent dans des milieux peu propices aux poissons convoités pour la pêche. Ces facteurs contribuent sans doute à la méconnaissance de sa distribution dans le nord du Québec, et possiblement sur la rive sud du Saint-Laurent vers l'est. Il est également possible que cette population d'Umbres de vase soit le fruit d'une introduction volontaire ou accidentelle par des pêcheurs les ayant prélevés plus au sud, dans le but de s'en servir comme appâts de pêche. Des inventaires mieux ciblés permettraient de préciser la distribution de cette espèce au Québec.

Remerciements

L'auteur remercie Julie et Félix Soucy pour leur aide sur le terrain.

The Mink Frog, *Rana septentrionalis*, in Southeastern Labrador

JEAN-FRANÇOIS DESROCHES[1], ISABELLE PICARD, and JOHN E. MAUNDER[2]

[1] Cégep de Sherbrooke, Département des Techniques de bioécologie, 475 du Cégep, Sherbrooke, Québec J1E 4K1 Canada, e-mail: jean-francois.desroches@cegepsherbrooke.qc.ca

Desroches, Jean-François, Isabelle Picard, and John E. Maunder. 2006. The Mink Frog, *Rana septentrionalis*, in Southeastern Labrador. Canadian Field-Naturalist 120(2): 239-240.

Mink Frogs (*Rana septentrionalis*) were collected at three new localities in southeastern Labrador in 2003 and 2005, extending the known range of the species about 200 km to the east, to the limits of the coast.

La Grenouille du Nord (*Rana septentrionalis*) a été trouvée dans trois nouvelles localités dans le sud-est du Labrador en 2003 et 2005. Ces mentions élargissent l'aire de répartition connue de l'espèce d'environ 200 km vers l'est, aux limites de la côte de l'Océan Atlantique.

Key Words: Mink Frog, *Rana septentrionalis*, range, Labrador.

The Mink Frog (*Rana septentrionalis*) has the most northerly southern limit of any North American anuran (Hedeen 1986). This southern limit ranges from southern Manitoba and northern Minnesota, south and east through Wisconsin, northern Michigan and southern Ontario, then northeast through northern New York, northern New England, New Brunswick, and Nova Scotia (Conant and Collins 1998; Cook 1984; Hedeen 1986). The species has recently been introduced on the island of Newfoundland (Warkentin et al. 2003). Its northern limit remains poorly known, largely because the species is particularly aquatic (Hedeen 1986) and its call and appearance are unfamiliar to many observers. In Labrador, the Mink Frog has been documented from several scattered localities, though not from the extreme north or southeast (Maunder 1983, 1997; Cook 1984; Desroches and Rodrigue 2004).

In 2003, during a primarily botanical and malacological field trip for the Provincial Museum of Newfoundland and Labrador (JEM), and in 2005, during a vacation trip (J-FD and IP), we surveyed ponds and brooks along all of the main roads and smaller town access roads of southeastern Labrador, as far to the northeast as the town of Cartwright.

On 3 August 2003 a single adult Mink Frog, found freshly dead from unknown causes, was collected (NFM HE-250) from the shoreline of a medium-sized pond, located beside the access highway running between the Trans-Labrador Highway and the town of Cartwright, about 39.5 km southwest of the road junction to the town of Paradise River (53°09'52"N; 57°31'56"W). This locality was, at the time, about 100 km east of the known range of the species (number 1 in Figure 1). The water of the pond was clear.

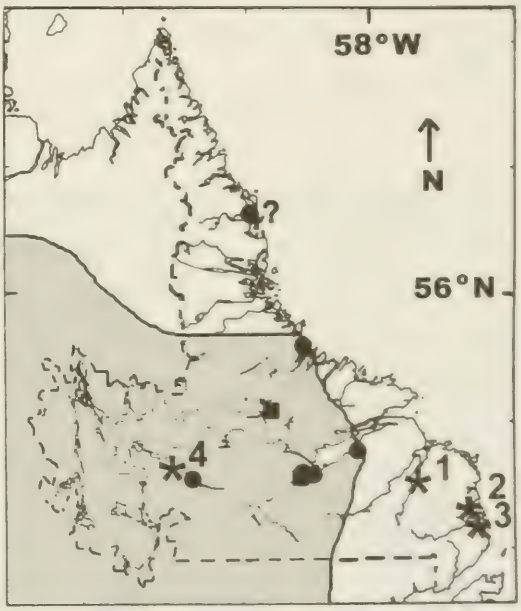

FIGURE 1. The Mink Frog in Labrador. Previous records: dots (Maunder 1983) and squares (Maunder 1997). Question mark: Questionable record (see Maunder 1983: 42, 44). Gray zone: proposed distribution based on previous records (Bleakney 1958; Cook 1984; Desroches and Rodrigue 2004). Stars: New records in southeastern Labrador (1: southwest of Paradise River, 2: Charlottetown, 3: St. Lewis, 4: east of Churchill Falls). Broken line: Labrador-Québec border.

The dominant emergent plants were Yellow Pondlily (*Nuphar variegata*), Narrowleaf Bur-reed (*Sparganium angustifolium*), and Water Lobelia (*Lobelia dortmanna*). The shoreline of the pond was mainly gravelly, over a boulder substrate, and was well-vegetated. The surrounding habitat was *Kalmia* scrub heath, with patches and strips of low Black Spruce (*Picea mariana*) woods in more sheltered areas.

In 2005, Mink Frogs were observed at two additional localities in southeastern Labrador, about 200 km east of the former known range of the species (numbers 2 and 3 in Figure 1). On 11 July, a subadult Mink Frog was collected (CMN-35805) from a small pond located beside a gravel road in the town of Charlottetown (52°46'09"N; 56°06'59"W). The pond was about 60 × 15 m in size, and had clear water, a muddy bottom, and grassy and rocky shores. Trees at the site were mostly Black Spruce. On 18 July, two Mink Frog tadpoles were collected (CMN-35810) by dipnetting at Blue Hill Pond, St. Lewis (52°24'55"N; 55°55'45"W). The pond had clear water, a sandy and rocky bottom, and some emergent plants near the shore. It was bordered by Sweet Gale (*Myrica gale*) and alder (*Alnus* sp.), and the adjacent forest was dominated by Black Spruce. Two Threespine Sticklebacks (*Gasterosteus aculeatus*) were caught in the same habitat, but released.

In 2004, an additional observation of the Mink Frog was recorded at St. Lewis by Christian Fortin (Fortin 2005) but no voucher specimen was collected (C. Fortin, personal communication).

In 2005, Mink Frogs were also observed in western Labrador, near the site of an old record, along the Trans-Labrador Highway, east of the town of Churchill Falls (53°29'29"N; 63°40'06"W) (number 4 in Figure 1). Two adults and one subadult were collected (CMN-35798). Although this observation is not a range extension it is included here because it is a new collection record.

During our searches for amphibians in southeastern Labrador, the only other species observed was American Toad (*Bufo americanus*). Tadpoles of this species were seen and/or collected at five locations along the roads.

The new Mink Frog collections recorded in this paper show that the species is more widespread in southeastern Labrador than has been previously documented. Further Labrador surveys should emphasize areas north of the presently known distribution of the species.

Acknowledgments

The authors thank Frederick W. Schueler for comments on the manuscript before submission, and Francis R. Cook for useful comments on the submitted manuscript.

Balkwill, Darlene, Brian W. Coad, Ismael Galvez, and John Gilhen. 2006. First record of the Great Barracuda, *Sphyraena barracuda*, from Canada. Canadian Field-Naturalist 120(2): 241-242.

We report the collection, and provide a description, of the first Great Barracuda, *Sphyraena barracuda*, in Canadian waters based on a partial skeleton from Country Island, Nova Scotia.

Key Words: Great Barracuda, *Sphyraena barracuda*, new record, fish fauna, Nova Scotia, Canada.

The cranium, lower jaw and attached trunk vertebrae of a Great Barracuda, *Sphyraeana barracuda* (Family Sphyraenidae), were found dried on a beach on Country Island, Guysborough County, Nova Scotia at 45°06'00"N, 61°32'37"W in May 1999 by Ismael Galvez. This is the first record for this species from Canada (Scott and Scott 1988; Coad et al. 1995). The specimen is catalogued in the Nova Scotia Museum of Natural History, Halifax, under NSM 85385.

Description

Three species of barracuda are reported from the western Atlantic Ocean north of Florida, *Sphyraena barracuda* (Walbaum, 1792), *S. borealis* DeKay, 1842, and *S. guachancho* Cuvier in Cuvier and Valenciennes, 1829. Only *S. borealis* has been recorded from Canada, a single specimen from Halifax Harbour, Nova Scotia, caught on 5 October 1928 (Scott and Scott 1988). Carpenter (2002) records *S. barracuda* and *S. guachancho* from Massachusetts (rare) southwards.

Our specimen is neither *S. borealis* nor *S. guachancho* on the basis of length, these two species generally reach maximums of 46-50 cm, (commonly) 35 cm and 50-60 cm, respectively (De Sylva 1984; Robins and Ray 1986; Carpenter 2002). Murdy et al. (1997) give 1 m for the latter species. Our specimen is close in size to a disarticulated specimen of *S. barracuda* in the Royal Ontario Museum (ROM R6281; pur-

FIGURE 1. Photograph of skeletal remains of a Great Barracuda from Country Island, Guysborough County, Nova Scotia (NSM 85385)(bottom) with skull of ROM R6281 above.

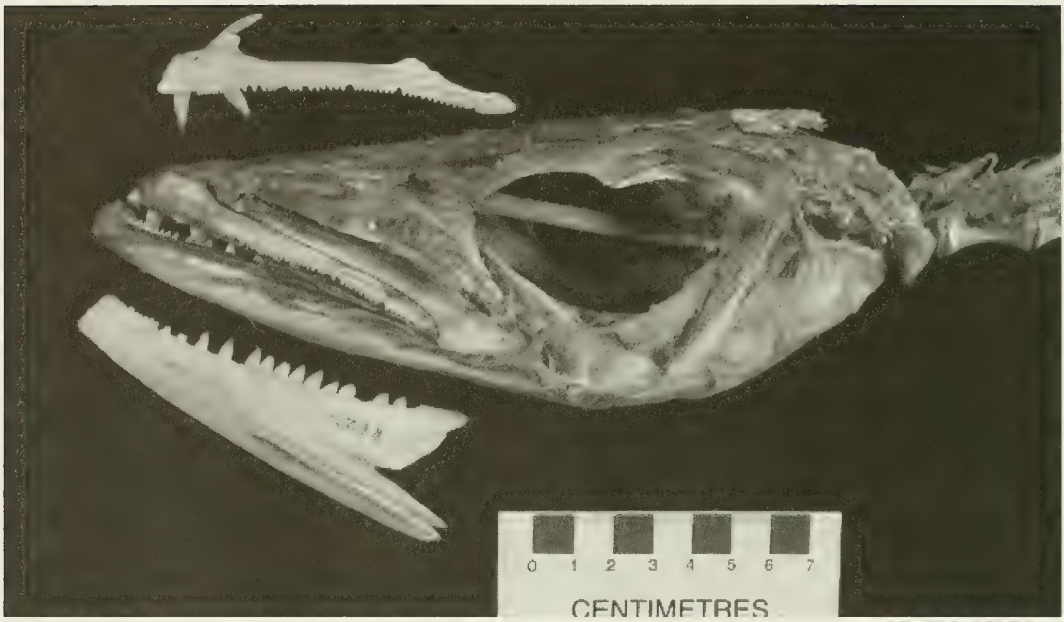

FIGURE 2. Photograph of skeletal remains of a Great Barracuda from Country Island, Guysborough County, Nova Scotia (NSM 85385) flanked by the upper and lower jaws of ROM R6281.

chased from Kensington Fish Market, Toronto, and thought to be from the Caribbean area) that has a recorded total length of 86.0 cm. The length of the dorsal skull surface (from the anterior tip excluding the upper jaw to the origin of the supraoccipital crest) is 135.1 mm in NSM 85385 and 116.8 mm in ROM R6281. These measurements make the Nova Scotian specimen ca. 99.5 cm total length. NSM 85385 has a head length of ca. 181.7 mm (the opercular bone is somewhat curved) and FishBase (www.fishbase.org) states that head length is 17.7% total length, giving a total length for the Nova Scotian specimen of 1.03 m. These two forms of measurement agree, making the Nova Scotian specimen about 1 m long in life. This unequivocally eliminates *S. borealis* and probably *S. guachancho*.

Other, osteological, characters also strongly suggest the Nova Scotian specimen is a Great Barracuda. The specimen has the area between eyes flat (convex in *S. guachancho*), teeth are contiguous, vertically flattened and erect (conical and widely spaced in *S. borealis*, angled backwards in *S. guachancho*), and the tip of the maxilla reaches past the anterior orbit margin (not reaching the orbit in *S. borealis*) (De Sylva 1984; Murdy et al. 1997; Carpenter 2002; comparative material of *S. guachancho* ROM R1837 and R2706).

We consider it unlikely that this specimen came from a local fish market and was imported. One of us (JG) has not seen this species on sale locally. The shore of Country Island is remote from commercial sites. It probably represents a stray that died in Canadian waters and was washed ashore.

Acknowledgments

We are indebted to Kevin Seymour, Department of Palaeobiology, Royal Ontario Museum, Toronto, for the loan of comparative material. Photographs were taken by Alison Murray, Canadian Museum of Nature, Ottawa, who also provided osteological advice.

ZOOLOGY

Animal Skulls – A Guide to North American Species

By Mark Elbroch. 2006. Stackpole Books, 5067 Ritter Rd., Mechanicsburg, PA 17055. 727 pages, $34.65 Paper.

As an instructor of comparative vertebrate anatomy, and a self-proclaimed enthusiast of skulls, I very much looked forward to reading and reviewing this book. I learned a fair amount from this book, mostly regarding animals that don't live in my area, so overall, this book was for me, a valuable read.

There is an enormous amount of material synthesized in this book. There are the expected figures illustrating the skull bones from a number of species; neighbouring figures illustrate the measurements most commonly used. However, the figure for reptiles has several errors, and those for the birds and mammals also have a few...not a good start for fundamental material near the beginning of the book.

Skulls of each species are illustrated in three views within the species accounts. Elsewhere, montages of dorsal views (mammalian and herp crania) and lateral views (mammalian mandibles, birds) are quite useful, and where practical, are illustrated at life-size. Even though the skulls in these montages show less detail than in the species accounts, I've always found this set-up useful (as in the *Golden Field Guide to Birds*, where warblers and sparrows are illustrated in a similar manner).

There are a number of issues that I found annoying. Why, for instance, is the Mantled Howler Monkey described (and illustrated along with two other species of non-human primate)? They are native to Central and South America; Are they feral in North America? We are never told. We are never told of the distributions of any of the animals, a shortcoming if someone is trying to identify a skull they've found based on this book. Secondly, the author is somewhat free with his use of the word *bone*. "Occipital condyles", for instance, are *processes* of bones, not bones unto themselves, though that is how they're treated. In a book that thankfully retains appropriate terminology, this oversight will be undetected by the novice, but irritating to the experienced. I now need to shout..."Molars are not flat!" I have to remind my students of this constantly. In English, we have the two words, "flat" and "broad", and they are not interchangeable. Molars adapted for grinding vegetation are broad...they are anything but flat as erroneously described numerous times in this book. There are a few other annoying errors in this vein. Given the number of prominent, pre-publication reviewers mentioned in the acknowledgements, one must wonder about their diligence to this project.

The title is awkward, *Animal Skulls* (as opposed to part two in the series, *Plant Skulls*?)...and misleading...*a guide to North American Species*: fish are not covered at all, amphibians and reptiles are given a token amount of space (12 species, fewer than 3% of those in North America), birds (71 species, 10% of breeders) are allotted only a fraction of the coverage of mammals (143 species, one-third of known species), this despite the fact that the number of species of birds alone outnumbers those of mammals in North America. I do understand that there is very little variation in skulls amongst warblers or sparrows, for example, and illustrating each species could quickly become redundant. However, the mammalian bias is still overwhelming.

The mammalian dominance in this book is also reflected in the amount of text devoted to each species account – one *line* for each herp, one paragraph for each bird, four or more paragraphs for mammals. About 100 pages of measurement data are provided for mammals (which is wonderful), though none is provided for the others. One is forced to ask, "Why bother with the birds and herps at all?" The same amount of space could have been used to make a more complete book focussing on mammal skulls alone. Then, subsequent volumes addressing other taxa could complete the series.

I particularly liked the early chapters on interpreting form, marks on skulls (from gnaw marks to bullet holes) and preparing skulls. These chapters were informative and well-written. For me, a large part of the worthiness of this book was in these early chapters. That is not to diminish the worthiness of the mammalian species accounts, they too are thorough and instructive.

A Field Guide to North Atlantic Wildlife

By N. Proctor and P. Lynch. 2006. Yale University Press P.O. Box 209040, New Haven, Connecticut 06520-9040 USA 221 pages. U.S. $19.95 Paper.

This book arrived on the morning I left for Svalbard in the Norwegian arctic. While the area covered by this book, offshore from North Carolina to Newfoundland, is some distance from Norway, the two areas do share a lot of wildlife. So I took the book along to make direct field comparisons.

I like the author's concept for this guide. He has selected the most likely species you have some possibility of seeing on a pelagic trip or ferry crossing in the northwestern Atlantic. This includes the large 'plankton' and algae, fish, turtles, whales, seals and seabirds. Only the more common species are included, enabling the authors to keep the book small [18 × 11 × 1.5 cm] and portable. This meant I was able to identify Beroe's Comb Jelly, Fin Whale and Ivory Gull carrying only one guide. The guide does not include coastal species such as crabs, molluscs and inshore fish.

The descriptions are well written. For example, the text for Fin Whale is a version of the classic descriptions found in many guides. I compared this to a whale that circled the ship and the information given was accurate down to the details of the back chevrons.

I had far more problems with the illustrations. First there is no attempt to show scale. A 10-inch flying fish is shown as the same size as an 18-inch species. This is a critical characteristic for look-alike species such as Glaucus and Iceland gulls. You need to check the text to see that there is a 5-inch difference in size. Similarly the Northern Seal plate shows the tiny 4 foot Ringed Seal as the same size as the 9 foot Hooded Seal. I found this disconcerting.

Some of the species shown are really cold water arctic animals. The North Atlantic is the southern fringe of their range. This is not mentioned for animals like Beluga, Dovekie or Harp Seal. I think giving their typical range would add perspective and could be said in few words.

The non-bird illustrations were very good. The artist has captured the short face of the Ringed Seal and the longer-nosed head of the Harp Seal very well. The fish portraits from the warm-water Dolphin [the fish] to the cold-water Cod are accurate.

The bird illustrations are another story. For example, the illustration of the Arctic Tern looks almost identical to that of the Common Tern. The Arctic has a shorter head and a longer tail giving it a different fore-and-aft look from the Common. The wing pattern is also quite different, having less black and giving the Arctic a much paler appearance. I had similar issues with other confusing pairs [Leach's and Wilson's storm-petrels, Glaucous and Iceland gulls, Audubon's and Manx shearwaters, etc.] Many other species lacked the subtle plumage differences that help confirm identification. For example, the two-toned grey on the wing of a Kittiwake and the armpit marks on the murres. Many birds are shown in winter plumage only. This is a reasonable approach as many birds disappear inland or north to breed. However, the winter Atlantic Puffin is very odd and the loon illustrations do not capture these birds at all well. It appeared that the artist did not have field experience with these species.

This is, however, a useful little book. If you are a novice I would recommend you take this book plus a modern bird guide on your pelagic trips. For more experienced bird watchers this book will suffice to remind you of the key points for what you may see and will be useful for all the non-bird species.

I thank Dr. Tom Smith, a fellow traveller, for sharing his immense knowledge of arctic wildlife, and thereby contributing to my review.

A Complete Guide to Arctic Wildlife

By Richard Sale. 2006. Firefly Books, 66 Leek Crescent, Richmond Hill, Ontario L4B 1H1 Canada. 400 pages. $49.95 Paper.

This is a comprehensive field guide to the birds and mammals of the Arctic. Author Sale describes the ecology and people of the region along with some Arctic history. He cannot avoid discussing both climate change and the threat of pollution. Short chapters on geology, geography and biogeography set the background. These are followed by the main text: a field-guide style section on the Arctic's mammals and birds. The information provided covers identification, size, voice, distribution, diet, breeding and taxonomy. The guide is illustrated with photographs supported by some field-guide style plates. Each species has a range map showing their circumpolar ranges.

I am always delighted to find a book that shows birds and mammals from a bio-regional perspective. Last summer I saw eight Snow Geese on the west coast of Svalbard – an unusual sighting. When you look at the distribution of the birds it is not hard to see how their expanding population could spill over the now unfrozen ocean a short distance eastward. This kind of perspective is difficult to reach when you use guides based on a political boundary (birds of Europe, Russia etc.)

The author's first problem was the difficultly of defining the boundary of the Arctic. He uses, in my opinion, the most sane choice. He has taken the 10°C July

isotherm, modified by extreme winter temperatures. This still leaves out some areas that I think of as "Arctic" such as James Bay and its Polar Bears and the northwest coast of Alaska with Belugas and Yellow-billed Loons. This, perhaps, proves that nature will never entirely fit into our human need for definitions.

Following his definition, the author then chose the species to be included as arctic birds and mammals. Here I am a little perplexed. He has, for example included Carrion Crow but not Black-billed Magpie (which I have seen at 63°N). He has only an introductory mention of the Gray Jay, which ranges to the shores of the Arctic ocean. Tree Swallow is given an individual account while the more northerly Cliff Swallow (I have seen it at 73°N) is merely mentioned as a rarity. I am also confused by the species he has decided to split and those he leaves as sub-species. For, example he has Iceland and Thayer's gulls as separate species but not Mew and Common gulls. There seems to be better evidence to split the latter. Similarly you can question having separate entries for Black and Common scoters.

These are minor points and not as significant to my two major concerns. The species descriptions are detailed and clear and are some of the best I have read. While they are first rate, the author gives exceedingly spartan information on confusing species. This is in contrast to the descriptions, which often allude to an important field mark. For example, he states the three central tail feathers of the jaegers are "distinctive." In the field separating a Parasitic Jaeger with a 9 cm tail extension from a Long-tailed with a 12 cm extension is not that easy. I well remember a controversial bird that needed the late great Earl Godfrey's talents to resolve as a Long-tailed Jaeger. Similarly the information on the Common and Hoary redpolls is not enough for field separation. There is no mention, for example, of the stubby bill of the Hoary – very evident in the nice accompanying photo.

My second point is that this is not a complete guide to wildlife. Unlike such books as Les Beletsky and Dennis Paulson's *Ecotraveller's Wildlife Guide to Alaska* it does not contain any information on plants, insects, marine invertebrates and fish or amphibians. Admittedly Beletsky only includes the commoner, more visible species although his title does say it is a complete guide, but he does include a broad spectrum of the wildlife, other than birds and mammals, visible to the naked eye.

While this in not meant as a coffee table book the photographs are really eye-catching. The bird plates are quite good, but I was less taken with the mammal plates. My chief reservation about all these illustrations is they frequently show only adult males.

I will take this book with me on my upcoming trip to the Pribiloffs. For the most part I will be seeing wildlife that I am familiar with and I will not carry a conventional field guide to the birds or mammals. This book will provide me with more encyclopaedia-style information about the creatures I am seeing. I will also take Beletsky and Paulsen's book and a flower guide.

2193 Emard Crescent, Beacon Hill North, Ottawa, Ontario K1J 6K5 Canada

The Black Flies (Simuliidae) of North America

By P. Adler, D. Currie, and D. Monty Wood. 2004. Royal Ontario Museum, 100 Queen's Park, Toronto, Ontario M5S 2C6 Canada, and Cornell University Press. 941 pages. $99.95 US.

This is a huge book. It is huge in size, filling 941 pages. It is huge in scope, treating the biology, management and identification of the entire black fly fauna of Canada, the United States, and Greenland. And it is huge intellectually, the culmination of many decades of work by an enthusiastic international community of researchers, among whom the authors of this book are prominent members.

In the preface, Peter Adler states that the book is "geared to a general readership." I would not have guessed that this was true, at first glance, but after some perusal it seemed to me that the book would be useful from about the undergraduate level on up. The writing is clear and precise, but the vocabulary will be daunting for most people without biological training. I suspect that the book will find a place in almost all scholarly libraries, and that the specialists who will use it most probably ordered a copy before it came into print. But there is a wider audience for the book as well, and in this regard I predict that it will be a required reference for many decades to come. The authors mention its relevance to medical and veterinary entomologists, aquatic biologists, environmental consultants, systematists, naturalists, pest management specialists and students, but I suspect the real list will be longer than that.

The text is arranged in four parts, covering background information, biology of black flies, economic concerns, and systematics and taxonomy. The first part provides an overview of the subject, a very readable history of the study of black flies (with lovely historical photographs) and a chapter on techniques for collecting and curating black fly specimens. As an entomologist (with no particular interest in black flies, I'll admit) I nonetheless found this section very interesting.

The second part of the book deals with the biology of black flies, and consists of a fine treatment of the structure of these insects (and their immature stages), as well as a well-written overview of their cytology. Black fly cytology was pioneered by the late Klaus Rothfels, a man deeply missed by the authors, and who they refer to as "friend, mentor, and phenomenon." A chapter summarizing the life history and behaviour

of black flies is also offered, along with an exhaustive summary of blood feeding host records, and records of black fly diseases and parasites.

For most readers, it is likely that the third part of the book, which treats the management of black fly pests, will be the most interesting. I can see this part of the book providing fodder for any number of term papers, research paper introductions, and consulting and government reports. I was surprised, however, to find that the chapter on management (Chapter 8) was largely historical in nature, without a summary of control recommendations. On careful reading, however, I could see the reason for this approach. Oil-based pesticides, DDT, and other chemical controls for black flies have not stood the test of time. The authors summarize the use of the bacterial toxin *Bti*, but give it only a qualified nod, with the caution that it too might lose its effectiveness over time. The chapter ends in an interesting discussion of repellants, and repellant clothing.

The fourth and final part of the book is clearly the section closest to the authors' own interests. It treats the 254 species of "North American" black flies, thoroughly. The focus is not simply on identification, it is also deeply phylogenetic, and includes a very careful evolutionary justification for each and every level of the classification. This is followed by a superb species by species treatment of the entire fauna. Significantly, there is additional information on the economic significance (if any) of each and every species, adding greatly to the summary in part three of the book.

As a non-specialist, I have to admit that the most impressive aspects of the book to me were the illustrations. They begin on page 436 (well before the halfway mark) and they are so masterfully executed that I couldn't help but come away thinking that there was something deeply beautiful and elegant about black flies, their larvae and pupae, and the fine details of their anatomy. More full-body illustrations of the adults would have been nice, but the overall sameness of the other life stages illustrated convinced me that side-by-side comparisons of the adults might not be all that useful. Maps follow the illustrations, and treat the United States and Canada on a county level, but they do not show Greenland. And, as one might expect in a book of this nature, the reference section and the indices are exhaustive.

This is a *magnum opus*, and a tremendous labour of love. It ranks, in my opinion, right up there with Holldobler and Wilson's *The Ants*. Having said that, it seems to me a shame that the book appears to have been presented as a somewhat impenetrable scholarly tome, without a showy slip cover, and with little or no fanfare for the "general readership" to which it was addressed. Don't be scared off by the size, or the complexity of this book. It is a masterwork, and if any aspect of your interests overlaps with the subject of black fly biology, do consider adding this fine volume to your library.

Insects: Their Natural History and Diversity: With a Photographic Guide to Insects of Eastern North America

By Stephen A. Marshall. 2006. Firefly Books Ltd., 66 Leek Crescent, Richmond Hill, Ontario L4B 1H1 Canada. 720 pages. CDN $95. Hardcover

It has always been said that you can't judge a book by its cover, but after reading *Insects: Their Natural History and Diversity* I've learned that this well-worn idiom isn't always true. When this book first crossed my desk, to say that I was instantly enamoured would be an under-statement. It was so beautiful, the cover adorned with a stunning jewel-toned dogbane beetle (*Chrysochus auratus*). I almost didn't want to crack the binding. However, my curiosity finally got the better of me and I'm glad it did because once I started reading I couldn't put the book down.

Visually stunning, with over 4000 colour photographs of insects in their natural habitats, *Insects: Their Natural History and Diversity* has the look and feel of a glossy coffee table book while still being full of accurate, well researched information.

As its title implies, *Insects: Their Natural History and Diversity* focuses on the diversity and natural history of common families of northeastern North American insects. The book opens with a brief synopsis of basic insect anatomy and morphology. This is followed by chapters covering the diversity of all insect orders, including all the major families, along with two chapters on non-insect arthropods and methods for observing, collecting and photographing insects. The book's last 50 pages are dedicated to illustrated keys to order and family as well as a key to the most commonly encountered insect larvae. These keys are designed to facilitate ease of use and therefore emphasize morphological characters visible to the naked eye or easily seen with a hand lens. Also peppered throughout the book are helpful suggestions on where to look for and find various insect orders/families. For example, "Depending on your inclination and the weather, a good place to start looking for assassin bugs would be in your kitchen light fixture. Unless you are much more

fastidious than most, the odds are that among the crispy critters accumulated there you will find a large black assassin bug called the Masked Bed Bug Hunter (*Reduvius personatus*)."

Considering that *Insects: Their Natural History and Diversity* is priced so as not to be cost prohibitive and is clearly written in plain language, it will be highly accessible to a broad audience, including naturalists, amateur entomologists as well as seasoned professionals. The author has also included a dollop of humour and wit throughout the text. For example, this passage describing the appearance of springtails: "Some are covered with scales, like those of a butterfly, many are brilliantly colored and all are morphologically bizarre, starting from the long, forked tail used to make Herculean leaps, and ending with the deeply pocketed mouth that makes springtails look like they have lost their dentures and then sucked on a bunch of lemons."

This book would make a great textbook for a natural history or general entomology course. Especially when you consider that the impetus for this book centres on materials originally gathered in support of the author's third-year course "The Natural History of Insects" at the University of Guelph. With its depth of scope and true to life colour photographs *Insects: Their Natural History and Diversity* would be indispensable in the field; however due to its size, it would be a bit unruly to have to lug around.

I thoroughly enjoyed this book and would recommend it whole-heartedly to anyone who has an interest in entomology, natural history or a simple curiosity about the six-legged world that surrounds us.

The Northern Goshawk: A Technical Assessment of its Status, Ecology and Management

By Micheal L. Morrison. 2006. Cooper Ornithological Society, Pennsylvannia.

The Northern Goshawk: A Technical Assessment of Its Status, Ecology and Management, is just as the title suggests, a highly technical assessment of the goshawk. I do not recommend it to those looking for a light read. Micheal L. Morris, editor, has compiled 22 recent journal articles that study the Northern Goshawk, focussing on ecology and population. Morris outlines two objectives for the assessment; the first is to summarize existing knowledge of the goshawk into one book, and the other is try to provide a framework for the development of future regional conservation and management strategies for the species.

Due to the legal issues surrounding the Northern Goshawk and its proposed listing as a *Species at Risk*, particularly in the United States, this book is a useful step for establishing what we do and what we do not know about this Accipiter. Unfortunately, it appears that the latter predominates.

Morris structures this assessment in an appropriate way, starting with an article that extensively covers the ecology of the goshawk, which helps provide the reader with a general knowledge of the bird. After this first article, the volume is divided into three distinct sections: Regional, Ecology, and Management, each of which contains a number of independent studies that Morris has gathered from several sources. Each of these studies take a highly regionally specific look at certain aspects of the Northern Goshawk. The goshawk has an extensive range over North America, Europe and Asia. As a result of this huge regional coverage there is extensive continental/regional variation amongst populations of these birds. This makes it difficult as a reader to distil any major trends between the articles. I found it hard to link many of the articles together because of the different styles by which the studies were carried out, as well as some differences of opinion. For example, Squires and Kennedy suggest that "[impacts from forest management] can either enhance or degrade goshawk habitat depending on type and extent of habitat alterations" (page 61). This is not so much a weakness of the assessment but rather the reality of goshawk management, and emphasizes the need for regional management strategies instead of an all encompassing global strategy, which is one of Morris's initial goals for the assessment.

Overall, this publication is a building block. It establishes where we have been in terms of goshawk management and conservation and makes clear where we need to head in the future. Morris has done a good job of selecting appropriate articles that clearly depict the challenges faced by researchers and the Northern Goshawk. I would recommend this book only to those who want to critically study goshawk ecology.

Turtles of the World

By Franck Bonin, Bernard Devaux, and Alain Dupré (Translated by Peter C.H. Pritchard). 2006. Johns Hopkins University Press. 416 pages. Illus., $50 (US).

First published in 1996 in French, this guide to the turtles of the world has been translated into English by eminent turtle biologist Peter Pritchard. In the translator's note, Pritchard acknowledges that he has also made some corrections and updates to the text. As such, the book includes recently discovered species such as *Pelusios cupulatta*, only described in 2003.

The book is divided into two sections: General Biology and Identification. General Biology provides a brief (nine pages) overview of the evolutionary history of turtles, their biology and conservation issues. Identification provides information on the approximately 330 recognized species of turtles. The species are grouped by families within the two suborders Pleurodira and Cryptodira. In general, each species account follows the same standardized format: distribution, description, natural history, protection. The species accounts vary from about half a page to three pages in length.

Each species also has a small regional map showing which part of the world the species occurs in and a larger, close-up map showing the distribution as shaded areas. These distribution maps also show major river systems, as well as some political boundaries. In addition, almost every species has one or more colour photographs.

Any attempt to list the names of all the species in the world of a certain group is a daunting task of sorting out sometimes conflicting and constantly changing taxonomy. The authors have accepted the recent splitting of the genus *Clemmys* and duly note this change in the appropriate species accounts. In contrast, the entire genus *Sternotherus* has been subsumed within *Kinosternon* without any explanation. While there has been debate over the validity of *Sternotherus* as a distinct genus, lumping the two genera goes against the current standard North American taxonomy. The authors are also somewhat inconsistent in assigning species status. They do not provide species accounts for *Chelodina mccordi* or *C. pritchardi* (although they are mentioned under the species account for *C. novaeguineae*), yet both these species are widely accepted. On the other hand, they elevate *Hardella indi*, a subspecies of *H. thurjii*, to full species status without any justification. This may explain why *Hardella indi* has the shortest species account in the book – three sentences.

There are some strange oversights in this book. The IUCN Red List of Threatened Species is the standard international ranking system for species at risk of becoming extinct. It designates status for these species from Lower Risk up to Critically Endangered. *Turtles of the World* occasionally mentions if a species has been "red listed," but not consistently, even within the same genus. For example, all four species within the genus *Acanthochelys* are on the Red List, yet the species accounts mention this for only one of the species. The book says one of the other species is on the "IUCN priority list" and the "IUCN is worried" about another. None of the species accounts provides the IUCN status, so the reader will not learn that *A. pallidipectoris* is considered the most endangered of the four species.

A thorough reference section is also lacking. The references for this book do not even fill two pages and almost all of the references are to other books on turtles. Accordingly, most of the information in the book is presented without any reference to a specific primary source. However, occasionally a statement is referenced and in almost every case that reference is absent from the reference section.

Of the Canadian species, the map for *Graptemys geographica* (Common Map Turtle) excludes the Ottawa area and all of the Quebec part of the range, and maps for both *Glyptemys insculpta* (Wood Turtle) and *Emydoidea blandingii* (Blanding's Turtle) omit Nova Scotia. *Terrapene carolina* (Eastern Box Turtle), a species never confirmed to have been historically present in Canada at all, is shown as ranging across all of southern Ontario as far north as Toronto. The range is also over-extended in Michigan, Ohio, Pennsylvania and New York.

Despite these criticisms this is a significant book in turtle biology. The photographs are often excellent. The natural history section, while sometimes too short, provides insight into an incredible variety of life history strategies. For many species, the contents of the protection section provide important information on threats, as well as a wide diversity of conservation measures. This volume is not the definitive statement on any of these 300+ species but it is a good introduction to the diversity of turtles.

DAVID SEBURN

Seburn Ecological Services, 2710 Clarenda Street, Ottawa, Ontario K2B 7S5 Canada

The Wolves of Algonquin Park: A 12-year Ecological Study

By John B. Theberge and Mary T. Theberge. Department of Geography, University of Waterloo, Waterloo, Ontario N2L 3G1 Canada. 163 pages. Available from bkevans@fes.uwaterloo.ca. $23.50 Canadian, $20 U.S.

John and Mary Theberge, a husband and wife team, have put together information available on wolves and their prey in one of North America's great ecosystems. Research results from the twelve year period (1987-1999) was used as a core for the publication. Student projects were as follows: 1 Ph.D. thesis, 7 MSc. theses, 11 BSc. theses). Overall, scientific publication of 55 papers is impressive. In the end, it was the Theberge's that pulled the material together into this single monograph. For that they need to be congratulated.

The results of the study are also based on previous work begun in the 1960s. The Theberges reached back in time and reanalyzed and re-evaluated some of the data collected earlier. A major portion of the review centred on the taxonomic study of Wolves in the park. They concluded that these canids were larger than the Coyote-Wolf hybrids to the southwest, smaller than wolves to the northwest. It reinforced earlier conclusions of the existence of "Algonquin type", "tweed type" and "boreal type" Wolves. New is the interpretation that these Wolves are taxonomically connected to the Red Wolf taxon, once more common on the continent to the southeast. In the "canid soup of genetics" these are many theories and assertions. So far there have been no clear indications of the "ultimate" position. Maybe none will ever emerge that will satisfy everyone who is interested in the subject. The Theberges have presented a convincing case.

Other portions of the monograph are equally well presented. There is much in the way of natural history – basic insight into the ecology of the predator within the prey dynamics dictated by geographical and botanical (habitat) setting. In an age of computers, abstract analysis and spurious mathematical modelling, this work stands out as a major contribution to science. It combines solid field work with a realistic quantitative assessment of the results, and I would recommend this as a case study for first-year graduate students who are contemplating a career in wildlife research. Beyond that, the study has had a real impact on conservation. In 2001, a total year-round Wolf killing ban in areas bordering Algonquin Park was announced by provincial authorities. Political responses were based on research results. It is a rare occurrence that this happens and it is a response to the well executed research. By any standard, that is a remarkable outcome to many years of dedicated work by scientists whose meticulous research and commitment to science were also coupled to a dedication to conservation and to bioethics. This is a scholarly monograph that likely will not be surpassed for many years to come.

At the outset the Theberges posed a series of questions that they wanted to find answers to. Likely some were listed after the fact, when intensive research results came in from the field work and data analysis. That too has strength. I cannot see much that has been left out. Appropriate photos and illustrations are found throughout the text. Some questions arose in my mind as to alternate explanations for some of the conclusions reached. Such results are inevitable and provide a useful basis for future scholars. This monograph is an exceptional document and has set a very high standard. I highly recommend it to anyone just starting field research on mammals, or for those veterans, who have spent much of their time in the pursuit of knowledge in the field of wildlife science.

BOTANY

Flowers – How They Changed the World

By William C. Burger. 2006. Prometheus Books, 59 John Glen Drive, Amherst, New York. 14228-2197 USA. 337 pages. US $23.00. Cloth.

Why are flowers important? They are not just for the viewing pleasure of humans, although they are spectacular – but why? This book will answer these questions. "Without the gift of flowers … man might still be a nocturnal insectivore gnawing a roach in the dark." It is often true that the more we know about something the more we appreciate it and the more we enjoy it. A book that leads to enjoyment is worthwhile, but this book also provides a much needed perspective on the flowering plants at a time when the world faces a biodiversity crisis. It contributes to an improved understanding of the natural world and a concern for the future. It is a very valuable contribution as well as a very enjoyable book that will appeal to anyone as a result of the friendly writing style.

William Burger, curator emeritus in the Department of Botany at Chicago's Field Museum, takes us on a journey to the discovery of how flowering plants have transformed the world. He begins with "What exactly is a flower?" which is a delightful and comprehensive introduction to flower morphology or what makes a flower a flower. Floral parts and their role are described in different kinds of flowers. It comes as a surprise to many people that the four bright white petals of a dogwood flower are not petals and the flower is actually an

aggregation of many flowers, that a dandelion flower is made up of dozens of flowers, that grasses do have very special flowers with floral parts analogous to those of tulips.

The book is full of fascinating anecdotes. Why are Wolves friends of plants? By 1926 Wolves had been extirpated in Yellowstone and Yogi, Booboo, and the other bears were of course more interested in picnic baskets than controlling the Elk so there were soon too many Elk and the vegetation began to change. Seventy-five thousand Elk were removed between 1926 and 1968 but it was not enough to get things back to the way they were – although it did maintain some plant diversity and kept the park green! Finally, in 1995 a human brain triumphed and thirty-one Wolves were reintroduced to Yellowstone and that quickly got things back to the way they were. There was less browsing pressure as "fear factor" came into play with Elk avoiding places where they were more likely to be ambushed by Wolves. Browsing was not only reduced, it was spatially variable, creating more niches for plants. The entire Chapter 2 is a very entertaining voyage though the annals of ecology indicating how plants are assisted and influenced by other organisms.

Flowering plants have a vast array of enemies, the herbivores, which are everything that eats plants, but they have developed chemical and mechanical defences. This is the subject of Chapter 3 "flowers and their enemies." It is full of the interesting stories that are known well to biologists but not to others – such as the central American Acacias that have a police force of stinging ants that emerge from the hollow thorns to attack intruders but also destroy the surrounding vegetation that competes with the Acacia. This is a mutually beneficial relationship. As well as a home in hollow thorns the ants are supplied protein by specialized leaf glands and sugar from other glands on the Acacia stems.

Chapter 5 "how are flowering plants distinguished" outlines the evolution of the distinctive features including tissues adapted to prevent water loss and to allow transport of water and nutrients and particularly the seed; which allowed land plants to achieve reproduction without external water, unlike ferns and frogs. Did you know that the simple, 120 million-year-old flower of *Archaefructus* has cast some suspicion on the evolution of flowers by reduction from Magnolia-like ancestors (contrary to what we told and regurgitated for the final exam a *few* years ago). The classification system, double fertilization and the evolution of fruit and many other complex phenomena are introduced in a clear and very interesting way. There is a wealth of information in this chapter and although it may be the most tedious chapter in the book, if you want to know what a plant is all about, you will not find a better general presentation of this information.

Chapter 6, "what makes flowering plants so special?" points out that flowering plants were not present in the forests of 300 million years ago (that made coal) but appeared 120 million years ago, were apparently little affected by the great extinction that wiped out the dinosaurs and other lineages, and became 87% of all plants today. The estimated 100-fold increase in the number of plant species since the Carboniferous period is mostly a result of the proliferation of flowering plants. The chapter explains why they are so successful and special in sustaining 99% of life on the planet. It may seem strange to find an explanation of photosynthesis in the same chapter as an explanation for the similarity of the floras of eastern North America and Japan, but the reader is definitely left with an idea of how special flowering plants are.

With the excellent introduction in these chapters the reader has developed a comprehensive knowledge of botany and ecology which provides a basis for the last two chapters, which indicate how flowering plants changed the world. Chapter 7, "primates, people and the flowering plants" explains how flowering plants created a world in which humans could live. The nectar, pollen, foliage and fruits together set the stage for a proliferation of insects and this led to the evolution of many new groups of insect eaters including the earliest primates, – but how did flatter faces, dextrous digits, upright stance and larger brains develop? It is all here. The chapter concludes with an explanation of how flowering plants and people came together to develop agriculture and how major civilizations rely upon flowering plants.

Of course flowering plants did not just create a world for humans, they also changed the world in many other ways and this is dealt with in Chapter 8, "how flowers changed the world." As they vastly increased in numbers they increased overall biodiversity. Biochemical specialization is explained with fascinating examples. Effect on the weather is considered including gradual cooling through carbon sequestration and the effect of grassland expansion. The chapter concludes with an outline of the effect of human actions on flowering plants and their impact on the world. An epilogue outlines the responsibility of humans with regard to protecting and managing plant diversity and preserving the world.

Following the epilogue is a series of notes 17 pages in length providing additional information sources for each chapter. This is an extremely useful section, vastly improving the educational value of the work, and it serves as an indication of the very extensive knowledge of the author. The book also has a colour insert of 12 attractive plates. It concludes with a very useful glossary that defines terms such as carpel, caryopsis and cleistogamous. The index is very helpful.

Burger's book is definitely a journey. It pulls together a broad array of concepts into a developing theme of how flowering plants got us to where we are today. It offers a biological perspective including the basics

of botany, ecology and evolution combined into a picture of plants and people and ends with an evaluation of where we are and where we are going. If everyone read and understood this book – if everyone had the knowledge and the respect for life and the inquiring and sensitive mind of its author – we would be in a better position to save the world.

This book is an example of outstanding communication. It provides biologists with what they need to know to teach, but it is not just for the biologist, nor just for Americans who spend nineteen billion dollars annually on leisure-time activities related to flowers and plants – it is for anyone. Behind the provocative title is a beautifully written book describing what flowering plants are, how they have influenced the evolution of life, contributed to the origin of humans and enabled humans to become the masters of our planet with the responsibility to manage its resources properly. It is so far from being just another book!

PAUL CATLING

ENVIRONMENT

Guide to Deserts

By Andrew Warren and Tony Allan (General Editors). 2006. Firefly Books, 66 Leek Crescent, Richmond Hill, Ontario L4B 1H1 Canada. 240 pages. $19.95 Paper.

After reading this book I realised I have never been to "see" a desert. I searched for Scimitar-horned Oryx (northern Sahara). I marvelled at the marine life off the Peruvian-Chilean coast (Sechura-Atacama desert). I have visited the impressive Abu Simbel temples (Libyan desert). But I have not really looked at the desert for its own sake. This is a mistake I will not repeat. While I have not been completely unobservant there are many subtleties I have missed. In future I will look for zengens, desert pavement, inselbergs and yardangs.

Deserts is a neat, small book in which the author defines deserts and describes the climatic conditions that shape their landscapes. He gives examples of the different types of desert and illustrates the impact wind and – yes – water have had on the land and its inhabitants. There are six chapters on aspects of deserts and an atlas of the major desert areas. The chapters cover wildlife such as plants, invertebrates and mammals and how they are adapted to thrive in an arid ecosystem. The people of the desert, their food, clothes, homes, customs and religions are described. This is an important chapter with the current focus of news from the deserts of Badiyat Ash Sham (Iraq) and Dasht-E-Margow (Afghanistan). The authors explain the riches of the desert. Not just oil, but farming and mining. They also look at conservation issues and the damage done by human activity. After reading this material I am more convinced we need to re-assess the use of water for irrigation.

The atlas is really a field guide of the world's 14 major arid zones [Canada's minuscule desert in British Columbia is not mentioned]. In addition to a map there are descriptions of each area's key characteristics. This includes some history, the people and key issues as well as a physical description. The authors have written a special chapter on visiting deserts to encourage people to see these special places.

There are plenty of photos and illustrations. These have been chosen not so much as pretty pictures, but to illustrate the points in the text. They range from the stark beauty of Monument Valley, through the rock-cut ruins at Petra to simple depictions of dunes. They show the faces and costumes of Tuareg, Berber and Bedouin (but not Navajo or Apache). The author has not missed mine sites, luxury hotels or aerial views in making his selection. One photo supposedly containing Giraffe, Ostriches and Eland shows six Oryx, some distant gazelles (presumably Springbock) but no Eland.

This book is very interesting to read just because it puts deserts in perspective. For someone like me who goes to places looking for something special, this book gives added value to a trip. For all of us it gives a wonderful background on where desert's ecosystem fits in the world's biosphere. The authors have convinced me that deserts are important and I will pay more attention in the future. Buy this book for yourself.

ROY JOHN

2193 Emard Crescent, Beacon Hill North, Ottawa, Ontario K1J 6K5 Canada

Endangered: Wildlife on the Brink of Extinction

By George C. McGavin. 2006. Firefly Books Ltd. 192 pages. U.S. $35.00 Cloth

An ecologist could not help but be drawn to a book with the title *Endangered. Wildlife on the brink of Extinction*. seeking an update on the current state of the world's species at risk. Unfortunately McGavin's book does not provide a succinct analysis of current status, the impacts we should be most concerned about, geographic localities of concern and the likely future trends. Rather this coffee table book provides a piecemeal of "information bites" for fifty animal groups ranging from dogs and cats to salmon and songbirds.

The lengthy (50 of 192 pages) two chapter introduction on the "Nature of Extinction" and "The Sixth Extinction" could be a grade nine biology course covering the basics of evolution and human development from our hunter-gather roots, through our agrarian and industrial revolutions to an assessment of supply and demand harvesting of nature. Instead of a discussion of the ecological implications of the loss of species to ecosystem integrity, extinction is considered more in terms of the extent of human mourning and the likely curiosity of future generations about species that once existed.

The "Lost and the Last" chapter constitutes the central text starting with Monotremes and Marsupials. Typical treatment of species groups include general statements such as: "Platypus eggs are eaten by introduced red foxes and rats as well as by native predators such as lizards. Many echidna eggs suffer the same fate." This text provides no meaningful information on the status of even these most unique of creatures for which clear trends must surely be known. No consistent format is used to cover each animal group, for example within the sub-section Insectivores Insectivora the subtitles used could have been chosen at random: Sense of Smell; Desmans in Danger; Desert Moles; Rare and Restricted; and Solendon Capture. Often the information presented begs the question; What has this to do with wildlife on the brink of extinction? If general ecological information is to be presented it would have been better in a text box or sidebar as a special case study.

Much more information could have been conveyed by following a consistent format for each animal group with sub-headings that allowed the reader to move from one group to another building an understanding of the most threatened species, the number of species threatened within each group, the ecological implications of species loss, the key causes of species decline, likely future trends and actions required to reverse negative trends. Summary graphs, tables or pictorial representations are virtually absent, yet they too could have been used to convey large amounts of information in a simple repeatable format for each species group.

The most impressive aspect of *Endangered* is surely the figures but, while there are captions, the text makes no direct reference to the figures and text and figures are often unrelated. In the Prosimians group the text states: "The strangest prosimian is surely the aye-aye. Its wide eyes, pointed ears and thin bony fingers lend it a goblin-like appearance". No picture of the aye-aye is included, but pictures of the sifaka and loris are included with no information on their status.

There is considerable variability in the treatment of each species group with some written in a more authoritative style, Bats Chiroptera is one example where there is a logical organization of sub-sections and more information on extinction. Variability is also seen in how comprehensively each species group is covered and this appears unrelated to the extent of information likely available. For example, the monkeys species group includes less than one page of text while the amphibians group has four pages of text.

In summary, *Extinction* provides an enormous amount of anecdotal information that is interesting to read, but which is likely forgotten soon after having read it. The book leaves the reader with a sense of disaster for all creatures as a result of human activity (which may or may not be far off the truth) and attempts to deal with all the ills of humankind from switching off light bulbs to buying local produce. Unfortunately readers that might be inclined to read *Endangered* will likely come away knowing little more than they started with.

MISCELLANEOUS

The Reluctant Mr. Darwin: An Intimate Portrait of Charles Darwin and the Making of His Theory of Evolution

By David Quammen. 2006. Atlas Books/ W. W. Norton & Company, New York. 304 pages. $30.00 Cloth.

As naturalists, we never cease to be amazed by the myriad wonderful life forms in nature, be it the flowering plants that suddenly appear following snowmelt, the wide variety of birds that return north every spring, or the colourful mushrooms found each fall in our forests. However, the source of this very diversity may easily be perplexing: why are there so many species and how did they originate? The theory of evolution has gone a long way towards explaining these and related questions by means of a wealth of empirical and theoretical studies.

Evolution by natural selection as [formulated] proposed by Charles Darwin is one of the most important and far-reaching ideas ever formulated, as it provides the basic mechanism whereby evolution has created the enormous diversity of life. David Quammen's objectives with his book were to offer a concise yet insightful overview of the background, birth and development of Darwin's idea of natural selection, and to consider the reasons for Darwin's reluctance in making his theory public. Indeed, there were many reasons why Darwin might have wanted to keep his evolutionary views to himself. These included the fear of rejection from a science corps whose natural history was based largely on teleological ideals with foundations in religious agendas, as well as his personal relationship with his beloved wife Emma, a pious Christian. In the end, it was Darwin's receipt of a manuscript from Alfred Russel Wallace, who at the time was collecting beautiful bird and insect specimens somewhere in the Malay Archipelago, which prompted the eventual publication of *On The Origin of Species* in 1859.

Quammen outlines this momentous piece of history concisely and does not attempt to compete with other more exhaustive biographies that provide a more detailed and scholarly account of Darwin's idea. The result is a very readable book that, despite the fact that Quammen is not an academic scientist, is based on thorough research of original background material. Hence, this book follows in the tradition of Quammen's previous successes, most notably *The Song of the Dodo* (1996), his outstanding and award winning volume on island biogeography. Several interesting aspects of Darwin's life are also highlighted, such as his mysterious illness, characterized by dizziness, stomach pain, and bouts of illness, often flaring up under stressful conditions. Darwin spent weeks on end at health clinics, surrendering his body to coldwater treatments, hoping to rid himself of the persistent ailment. The book also describes a number of the small natural history experiments that Darwin performed to understand the mechanisms of evolution, such as submerging common vegetable seeds in brine solution to investigate the possibility of over water dispersal, or dangling duck feet in water to see if gastropods would climb aboard on a flight destined for other ponds. With these sorts of amusing passages highlighting the development of the most important idea in biology, *The Reluctant Mr. Darwin* should be of great interest to naturalists regardless of whether they are deeply aware of evolutionary theory or simply familiar with Darwin's work. The good quality of the material in this volume, along with Quammen's command of the English language, makes this book well worth the read.

JOHAN LINDELL

35 Charles Street West, Apartment 1408, Toronto, Ontario M4Y 1R6 Canada

A Field Guide to Gold, Gemstones & Mineral Sites of British Columbia, Sites Within a Day's Drive of Vancouver

By Rick Hudson. 2006. Volume 2. Revised Edition. Harbour Publishing Co. Ltd., P.O. Box 219, Madeira Park, British Columbia VON 2H0 Canada. 368 pages. 8 illustrations $16.95 CAD

Rick Hudson has succeeded in expressing his passion for mineral collecting through his field guide book. On a second level he also tries to promote a sense of adventure by teasing the reader to go out and explore or prospect for nature's buried treasures.

The author structured the book so the reader can easily cross-reference required information in the lengthy location lists. A "How to Use This Book" and a "Quick Reference Guide" help to quickly locate items of interest throughout the book.

The book cover illustrates the hobby of mineral collecting as a family activity. Hudson educates the reader from first principles on how to become a Rockhound. To accomplish this, he describes how to prepare yourself by choosing proper clothing, safety gear, collecting tools and maps. He warns the future mineral collector about natural hazards they may encounter such as; rattlesnakes, grizzly bears and ticks. Ethics, access rights and mineral rights are also discussed to keep the collector within acceptable collecting practices and to avoid unintentional trespassing.

Mineral collecting is attractive to many people because as you find an interesting mineral specimen, you want to learn how nature created it and or its geological history. The author included short geological descriptions partitioned by collecting areas as well as mining histories of local economic importance within the collecting area.

Colour plates illustrate the minerals found in some of the collecting sites and detailed occurrence maps are included in all the collecting area sections throughout the book. The colour plates represent minerals that are possible to find in the collecting sites. Government mineral index files were included in the locality information along with detailed road log descriptions.

The author has made a successful merger of personal knowledge and technical data to compile an informative volume which can provide years of enjoyment for many future rockhounds and their families and friends.

History of the Russian Zapovedniks 1985-1995

By F. Shtilmark. (Translated from Russian by G. H. Harper). 2003. Russian Nature Press (www.rusnatpress.org.uk). 307 pages, £30.95

This book makes a major contribution to the environmental history of Russia, its influence zone and also to the global nature heritage. The Zapovedniks - Russia's protected nature reserve system – have withstood the test of time, although it has been distorted by social and political factors. Due to the great English translation by G. H. Harper, the Russian Nature Press offers us new views on conservation, as well as solutions to the current problems with protected areas world-wide. The original text is written by one of the leading Russian environmental writers and fascinatingly energetic activists providing for superb inside knowledge unknown to the western world. His visions are guided by principles such as "we have a duty to make our zapovedniks and national parks the pride of Russia...".

In this great book the reader will learn about Russia's nature, and foremost, about how to protect it during such fascinating and complex times like Tsarism, the rules of Lenin and Stalin, and Gorbachovs' glasnost and perestroika (the book manuscript was finished 1996). Throughout the history of the Zapovedniks (in short called Zap's) the role of the Academy of Science proves very significant. The composition and attitude of its board members towards protection vs. exploitation play a crucial role for Zap-Management (and species survival).

Most readers will likely be surprised to learn that the Russian Zapovednik system actually acted as a model for setting up the global network of biosphere reserves. But to this very day there exists a fundamental confusion in the western world regarding the terminology and meaning of Russian protected nature reserves. As described over the 307 pages, western-style National Parks represent only one component in the complex Russian system of Zapodniks, Zapovednosts, Zapovednayes and Zakazniks. A critical view of the author refers to National Parks simply as pseudo-zapovedniks because "An absolute Zapovednik is an area of land or water that together with all products of nature on and in it (plants, animals, soils, rocks, minerals) is preserved in perpetuity and in a state of inviolability".

Many Zapovednys were originally used for the Tsars or as a prince's hunting estate, e.g., the famous Kuban Hunting Reserve. So originally, these systems go back to land grants from the aristocrats. But the author takes great care in explaining that Qualified Zapovedniks have a weaker definition in their protection status, allowing for human use. A Zapovednost implies the complete withdrawal of an area of land from any economic use. The biological theory of Zapovednosts rests on the idea of an ecological equilibrium, and the capacity of organisms to regulate themselves in the absence of direct human influence. Zapovedaniye means a withdrawal of a certain area of nature from the sphere of ordinary economic activity for the attainment of particular non-traditional economic, social and ecological purposes. It represents samples of "virgin nature selected for comparison with exploited land". Zapovedny Management relates to a method of managing protected territories and water bodies. Further, one can find Zapovednik Museums, as well as Game Zapovedniks and even Spa-Zapovedniks. Only the Zakazniks are areas set aside for hunting. Finally, the Etalons are protected areas, model examples, representative for a specific ecosystem type and completely free from human influence.

Several black/white maps, portraits, tables and diagrams are presented, and including with some painted Russian scenery, turn this publication into a precious book to own.

The book makes a nice case that fur-bearing animals were considered as Russia's "Soft Gold"; they were one of the chief resources for foreign income. This wealth created the influential Moscow Fur Institute. Besides the earlier over-exploitation of Russian beaver resources, the 20th century showed also a sharp decline of sable, and a subsequent nation-wide harvest moratorium was not really effective. Therefore, sable reserves were requested, and a Sable Zakaznik was set up by local people in Kamchatka as early as 1882. These Game Zapovedniks were called Superior Zapovedniks in which hunting was not allowed, and breeding programs were initiated.

As elsewhere in the world, the tensions around protected areas were intense. Borders of Zapovedniks were often not followed or defined even. Poaching was common in taiga Zapovedniks or where "old believers", Chinese bandits, and fur-traders lived. In Crimea and elsewhere, the designated Zap-guards and zoo-staff were tortured or even executed.

Besides the many day to day struggles in Zapovedniks, Lenin's revolution then had a massive restructuring in place for them, resulting in the "Socialisation of the Land". It converted the entire country in a gigantic "national park"; ownership rights were removed with one stroke. Lenin was a hunter himself and had a great interest in nature affairs. That proved to be fortunate for Russia's nature, as well as for some aspects of the global environment. From that point on, the Russian Soviet Federal Socialist Republic (RSFSR, founded 25th October 1917) played a crucial role in the protected areas, and started its well known enthusiasm for regulations.

Some Russian Zapovednik administrators used the guiding principle "Nature is not a cathedral, but a workshop". And typical Zapovednik tasks dealt with the introduction ("Acclimatisation") and control of animal populations. Culling was part of most Zapovedniks,

and the culled game meat was contributed to the social food-supply or else was sold to Zapovednik staff. The elimination of crows, and cormorants as fish-eating birds took place Russia-wide. Bears, marten, gulls, skuas, crows, hawks and eagles got killed *en masse*. Extensive campaigns against wolves by poison and air were carried out for almost a century shaping the Russian culture against predators to this very day.

The text reads like a crime story. As felt in many other places in the world, the Stalinist revolution further led to more and major changes. Namely, a shift from nature protection to exploitation in the interest of the socialist construction. Protecting nature for the sake of nature was not *en vogue* anymore. Further, "Bourgeois" professors who comprised a large proportion of the conservation's cadre in the Soviet state in the 1930s were eliminated, and many members of the Academy of Science got arrested. From then on, Zapovedniks were explored for minerals, coal and oil deposits, timber resources and fur bearing resources, culminating in slogans like "We must take the Urals apart". The fetish of inviolability as a bourgeois theory got sacrified. Protection was now defined as exploitation. Under comrade Stalin, Zapovedniks turned into multi-purpose economic enterprises. It led to the view that planned exploitation of Natural Resources would be the main pre-condition of Nature Protection.

From the 1960s onwards the Zapovednik system experienced a modernization. A. G. Bannikov and G. P. Dementev started to participate in the IUCN. Russian-Japanese international migratory bird conventions got signed. In 1970-71 the UNESCO biosphere reserves "Man and Biosphere" were established. In 1972 a U.S.-Russian agreement on protecting the natural environment got accomplished, and the USSR Red Data book came into place.

As early as 1975 multidisciplinary monitoring was demanded in Russia, a theme that is very relevant for today even, and not achieved by most countries yet. When cheap fuel got provided for that purpose to the Zapovedniks by the state, they got quickly swamped with motorboats, snow tractors and motorcycles. Helicopters can be added to the list as well since flying was very common by then. The author explains that caterpillars tracked and wheeled cross-country, and vehicles ploughed up the tundra on Vrangel and Taymyr.

In the 1990s, the U.S. American Soros and MacArthur Foundations with their foreign funds gained considerable influence over Russia's nature; WWF, Evraziya, the Japanese Society for the Protection of Birds, the Global Ecological Facility, and the International Bank for Reconstruction & Development were other international players accounting for as much as one quarter of Western money on the expenditure for protecting Russia's biodiversity. This foreign influence made many Russian politicians extremely uneasy.

However, despite all of these gigantic efforts, and similar to the case in North America, nothing remains of the many original habitats such as the steppe. "We now need to introduce the specially-protected areas system almost forcibly to counterbalance irrational natural-resource-use, and to prevent deterioration of landscapes and valuable sites".

It becomes clear from the text that Russia and its Zapovedniks etc. are not set up for the information society at all, and thus Russian high quality online (raw) data are hard to come by still. Much crucial biodiversity information is published though in hardcopy and journals, or exists in filing cabinets, private ownerships and cabinets, and as expert knowledge. Otherwise, check the Russian Conservation News found online www.russianconservation.org.

One cannot find a better and centralized overview of Russian conservation history issues than this book; its detailed Appendices are further assets consisting of current and former Zapovednik lists, a Kyrillic reference list and in-depth annotations for each chapter. I find that this book is a little too friendly on the widespread view in Russia that traditional Zapovednik management caters primarily to the Russian race but leaves natives and other ethnical groups out. Marine protected areas were apparently not really part of Russia's nature protection system either.

However, "Come back in hundred years, then let's talk" (And in the meantime, I highly suggest buying and reading this important book).

FALK HUETTMANN

Institute of Arctic Biology, Biology & Wildlife Department, University of Alaska-Fairbanks, Alaska 99775 USA

A Field Guide to the Identification of Pebbles

By E. Van der Flier-Keller. 2007. Harbour Publishing, Box 219 Madeira Park, British Columbia V0N 2H0 Canada. 9 inch by 8 inch pamphlet, $7.95

Professor Van der Flier-Keller has produced a neat pebble guide for children. She has condensed fundamental pebble geology into a single page. Then she portrays 34 types of rock as they appear when they are transformed into pebbles. She adds in a few man-made objects that also appear on beaches, such as glass. The pamphlet is a single long sheet of plasticized paper with clear, "life" size photographs of pebbles. It is easy to use and is ideal for children as it does not get over-complicated and therefore overwhelming. For example, it only shows two forms of granite – pink and white. This is quite sufficient for an 8-year old to absorb. While the author has reduced the text to a simple explanation she does use the correct technical terms throughout. Younger children may need help with some of the terms (plutonic) or concepts (glacial deposits), but then this is what parents are for. The pamphlet folds

to 4.75 inches by 9 inches and can readily slip into a pocket or glove compartment.

Although aimed at children this is a useful tool for the non-geologist adult who does not have the time (or inclination) to master the complex technology of geological science. I have a habit of picking up small rocks and pebbles from the places I visit. I have not been consistent in identifying them, but I am sure this pamphlet will help me improve.

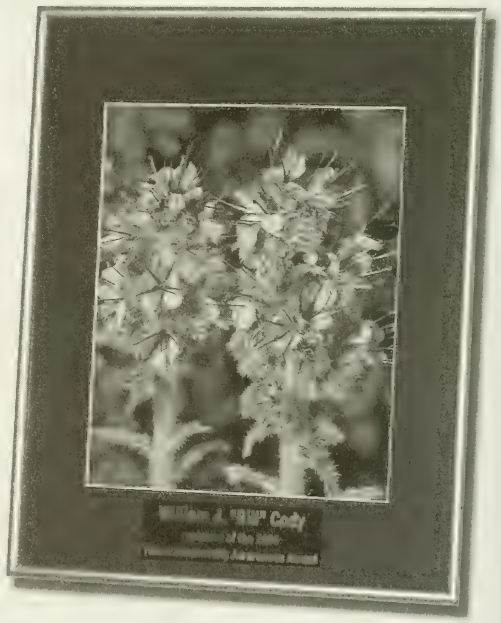
Herpetological Survey 2006 Atlas of Amphibians and Reptiles of Quebec

Instructions for participants in the 19th herpetological survey for the Quebec Atlas of amphibians and reptiles, coordinated by the St. Lawrence Natural History Society in collaboration with the Ministère des Ressouces naturelles de la Faune du Québec. This provincial inventory is done every year with the important cooperation of volunteers. Observation cards to fill out and details of information needed can be obtained from David Rodrique, Director, Research and Conservation, Program Coordinator, or Mathieu Oulette, Research and conservation, St. Lawrence Valley Natural History Society, Ecomuseum, 21 125 chemin Saint-Marie, Saint-Anne-de-Bellevue, Quebec H9X 3Y7; phone 514-457-9449, extension 105; fax 514-457-0769; e-mail: info@herpetofaune.org. Current information on The Atlas of Amphibians and Reptiles of Quebec is now available online at the St. Lawrence Natural History Society website: www.herpetofaune.org.

Bill Cody Receives Yukon Biodiversity Awareness Award

From 1946 to 1987 Bill (W.J.) Cody was employed with Agriculture and Agri-Food Canada as plant taxonomist and curator of Canada's largest collection of plants. From 1988 to 2006 he has continued to come in to work every day as an Honourary Research Associate and he has made a series of remarkable contributions to our knowledge of the plants of northwestern North America. His 643 page textbook on the Flora of the Yukon was published in 1996. It included current information on status, distribution, ecology, classification and identification. In 1997 this outstanding work was recognized with the prestigious Lawson Medal awarded by the Canadian Botanical Association. An updated second edition of the book was published by the National Research Council in 2000. Since his retirement Bill has published 14 articles on the flora of the Yukon in scientific journals. He has provided an enormous amount of information on plants to the agricultural sector, natural resources staff, wildlife biologists, native people and landscape planners. Always willing to help, he has identified a thousand plants from the Yukon every year. It is therefore not a surprise that Bill has been recognized for his outstanding service with the Yukon Biodiversity Awareness Award. The award honours those who have made major contributions to educating people about biodiversity and its importance.



Bill started as an assistant with the Canada Department of Agriculture in Ottawa. Twenty-one years later in 1967 he was made a Research Scientist. This classification was generally reserved for people who had a Ph.D., but Bill's outstanding accomplishments at that time were judged by his colleagues and the science arm of the federal civil service to warrant treatment at the Ph.D. level. The awards that Bill has received since then are numerous, but one in particuar draws attention his broad contribution. In November 2002 he received a Queen's Golden Jubilee Commerorative Medal. These medals were awarded to a limited number of people who have made a significant contribution to Canada, in this case "especially for his work on *The Canadian Field-Naturalist*, Canada's foremost scientific journal for field biology." Bill has served as the business manager, article and book review contributor, and manuscript reviewer for this journal for 60 years, and his influence on its development, support, improvement and content is beyond question.

Bill also served as curator of the largest dried plant collection in Canada from 1959 to 1988 and was largely responsible for its development. This collection of now over 1 million specimens has become a major tool of Agriculture and Agri-food Canada for plant identification.This collection provides a wealth of information that is needed to implement Agriculture and Agri-food Canada's Biodiversity Strategy and to respond to the International Convention on Biodiversity. It is particularly valued as a tool for improved plant classification studies used by researchers in other institutions both in Canada and worldwide. It is also important in protecting Canada's borders and enforcing federal regulations. Many thousands of specimens that Bill collected in the northern wilderness under extreme and dangerous conditions are part of this collection and serve as vouchers for his numerous publications and books.

Bill was born in Hamilton on 2 December 1922. His father was a doctor and his mother a nurse at Hamilton General. He grew up in Hamilton and received his B.A. from McMaster University in 1946.

The Yukon Biodiversity Awareness Award plaque that Bill received included a photo of one of Yukon's rarest plants, McBride's Phacelia (*Phacelia mollis*) which is a Beringian endemic (confined to the unglaciated area of Alaska and Yukon).

Text slightly modified from that provided courtesy of Paul Catling, Canada Agriculture and Agri-food, Ottawa. Photograph of the award plaque courtesy Stephen Daryshire, Canada Agricuture and Agri-food, Ottawa.

Editor's Report for Volume 119 (2005)

Mailing dates for issues in volume 119: (1) 6 June 2006, (2) 13 June 2006, (3) 30 November 2006, (4) 17 April 2007. A summary of membership and subscriber totals 2004 is given in Table 1. The number of articles and notes in volume 119 is summarized in Table 2 by topic; totals for Book Reviews and New Titles are given in Table 3, and the distribution of content by page totals per issue in Table 4.

Council continued to authorize 40% of membership dues for publication of the journal and all of subscriptions (both individual and institutional). Council also has allocated 80% of the annual interest from the Manning Fund and other capital funds to *The Canadian Field-Naturalist*. Use of the Manning fund portion was broadened on an issue-by-issue basis to offset the publication costs where author and institutional contributions were insufficient to cover page charges.

The journal was printed at Gilmore Printers, Ottawa, and thanks are due business representative Tom Smith, customer representative Chuck Graham for overseeing production, and Wendy Cotie for typesetting and corrections. Leslie Cody prepared the Index for volume 119; Elizabeth Morton proofed the galleys. Long-time (60 years) Business Manager for the journal, Bill Cody, gradually relinquished much of his active role during the year and some of his duties were shouldered by treasurer Frank Pope and assistant treasurer Jim Ward. Roy John processed books sent by publishers, assigned reviewers, edited book reviews and prepared the New Titles listing. Sandra Garland the Ottawa Field-Naturalists' Club webmaster, posted contents and abstracts from each issue as it appeared, and sent pdfs of articles and notes ordered by authors.

Manuscripts (excluding book reviews, notices, and reports) submitted to *The Canadian Field-Naturalist* totalled 75 in 2005, equalling the total for 2004. The following reviewed papers submitted in 2005 (with number of manuscripts reviewed in parentheses if more than one):

TABLE 2. Number of articles and notes published in *The Canadian Field-Naturalist* Volume 119 (2005) by major field of study.

Subject	Articles	Notes	Total

Advice for Contributors to *The Canadian Field-Naturalist*

Content

The Canadian Field-Naturalist is a medium for the publication of scientific papers by amateur and professional naturalists or field-biologists reporting observations and results of investigations in any field of natural history provided that they are original, significant, and relevant to Canada. All readers and other potential contributors are invited to submit for consideration their manuscripts meeting these criteria. The journal also publishes natural history news and comment items if judged by the Editor to be of interest to readers and subscribers, and book reviews. Please correspond with the Book Review Editor concerning suitability of manuscripts for this section. For further information consult: A Publication Policy for the Ottawa Field-Naturalists' Club, 1983. *The Canadian Field-Naturalist* 97(2): 231-234. Potential contributors who are neither members of *The Ottawa Field-Naturalists' Club* nor subscribers to *The Canadian Field-Naturalist* are encouraged to support the journal by becoming either members or subscribers.

Manuscripts

Please submit by post **to the Editor,** in either English or French, **three** complete manuscripts **written in the journal style.** Manuscripts may also be submitted (one copy) by e-mail. The research reported should be original. It is recommended that authors ask qualified persons to appraise the paper before it is submitted. All authors should have read and approved it. Institutional or contract approval for the publication of the data must have been obtained by the authors. Also authors are expected to have complied with all pertinent legislation regarding the study, disturbance, or collection of animals, plants or minerals. The place where voucher specimens have been deposited, and their catalogue numbers, should be given. Latitude and longitude should be included for all individual localities where collections or observations have been made.

Manuscripts should be printed on standard-size paper, **doublespaced throughout,** generous margins to allow for copy marking, and **each page numbered.** For Articles and Notes provide a bibliographic (citation) strip, an abstract, and a list of key words. Generally, words should not be abbreviated but use SI symbols for units of measure. The names of authors of scientific names may be omitted except in taxonomic manuscripts or other papers involving nomenclatural problems. "Standard" common names (with initial letters capitalized) should be used at least once for all species of higher animals and plants; all should also be identified by scientific name.

The names of journals in the Literature Cited should be written out in full. Unpublished reports and web documents should not be cited here but placed in a separate Documents Cited section. List the captions for figures numbered in arabic numerals and typed together on a separate page. Present the tables each titled, numbered consecutively in arabic numerals, and placed on a separate page. Mark in the margin of the text the places for the figures and tables.

Check recent issues (particularly Literature Cited) for journal format. Either "British" or "American" spellings are acceptable in English but should be consistent within one manuscript. **The Oxford English Dictionary, Webster's New International Dictionary** and le **Grand Larousse Encyclopédique** are the authorities for spelling.

Illustrations

Photographs should have a glossy finish and show sharp contrasts. Electronic versions should be high resolution. Photographic reproduction of line drawings, **no larger than a standard page,** are preferable to large originals. Prepare line drawings with India ink on good quality paper and letter (don't type) descriptive matter. Write author's name, title of paper, and figure number on the lower left corner or on the back of each illustration.

Reviewing Policy

Manuscripts submitted to *The Canadian Field-Naturalist* are normally sent for evaluation to an Associate Editor (who reviews it or asks another qualified person to do so), and at least one other reviewer, who is a specialist in the field, chosen by the Editor. Authors are encouraged to suggest names of suitable referees. Reviewers are asked to give a general appraisal of the manuscript followed by specific comments and constructive recommendations. Almost all manuscripts accepted for publication have undergone revision—sometimes extensive revision and reappraisal. **The Editor makes the final decision** on whether a manuscript is acceptable for publication, and in so doing aims to maintain the scientific quality, content, overall high standards and consistency of style, of the joumal.

Special Charges — Please take note

Authors **must share in the cost of publication** by paying $90 for each page, plus $20 for each illustration (any size up to a full page), and up to $90 per page for tables (depending on size). Authors may also be charged for their changes in proofs. Reproduction of color photos is extremely expensive; price quotations may be obtained from the Editor. If grant or institutional funds are not available, club members and subscribers may apply for a waiver of charges for the first five pages.

Limited joumal funds are available to help offset publication charges to authors without grants or institutional support. Requests for financial assistance should be made to the Editor when the manuscript is submitted.

Reprints

An order form for the purchase of repents will accompany the galley proofs sent to the authors. Invoices for publication costs will be sent when the submission is published.

Way, Jonathan G., Dean-Lorenz M. Szumylo, and Eric G. Strauss. 2006. An ethogram developed on captive eastern Coyotes *Canis latrans*. Canadian Field-Naturalist 120(3): 263-288.

We studied capture Eastern Coyotes (*Canis latrans*) from 27-585 days of age and compiled an ethogram on them. A total of 72247 15-sec samples were taken, amounting to 301 h of field time varying between 59.4–61.3 h per Coyote. A total of 540 behavioral patterns was observed amongst the 16 behaviour categories ranging from 9 (miscellaneous) to 72 (explore investigate) action patterns per parent category. The 16 parent categories that we believed best described and appropriately sorted the behavioural actions were resting, sitting, sitting1, sitting2, standing, traveling, explore investigating, hunting, feeding, infantile, greeting, self play, play initiating, playing, agonistic, and miscellaneous. Exploring accounted for >31% of all of the behaviours observed with resting and sitting (combined), standing, traveling, and play as categories decreasing in order of most to least frequent. Despite some omissions in our ethogram and drift associated with its ongoing development, we believe that the large amount of data collected made it rigorous enough to be a useful guide for the species. We argue that although future research will no doubt add to and/or modify components of it, its ease of use in the field (in captivity or in the wild) and it being the first complete ethogram described for the species, make it a useful tool for future researchers.

Key Words: canid, *Canis latrans*, eastern Coyote, ethogram, behavioural study.

The concept of an ethogram, also called action system (Makkink 1936), behavioural inventory (Bekoff 1972a, 1978), or behaviour pattern (Scott and Fuller 1965), is a durable tool for analyzing vertebrate behaviour and dates back to Jennings (1906), Makkink (1936), Tinbergen (1959), and Lorenz (1971). Although there have been direct observation behavioural studies of Coyotes (*Canis latrans*) in captivity (Snow 1967; Silver and Silver 1969; Bekoff 1972a, 1978; Parks 1979; Ryon 1986) and in the wild (Camenzind 1978; Bekoff and Wells 1981; Gese et al. 1996), there has yet to be a standardized and complete ethogram published for the species. Except for Goodmann and Klinghammer's (1990) non-peer reviewed but detailed manual which presents a Wolf (*Canis lupus*) ethogram and Scott and Fuller's (1965) ethogram on Domestic Dogs (*Canis familiaris*) (which they compared with literature on Wolves, Coyotes and Red Foxes [*Vulpes vulpes*]), we could not find any other study that described a full behavioural repertoire of any other of the approximately 35 canid species (Ewer 1973; Wozencraft 1989). Most studies examining behavioural data have focused on specific time periods (e.g., young pups/behavioural development – Bekoff 1972a, 1978, 1989), specific actions (e.g., social interactions – Fox 1970; Bekoff 1974; Zimen 1982), lumping behaviours into general categories (Silver and Silver 1969; Parks 1979; Gese et al. 1996), or describing many behavioural patterns but providing no summary or chart showing a complete ethogram (Mech 1970; Lehner 1978). Schleidt et al. (1984) termed these "partial ethograms" and stated the importance of publishing complete ethograms on as many species as possible. In addition, Macdonald et al. (2000) underscored the significance of developing ethograms on different species by stating that without one, meaning is not fixed. As such, ethograms are vital reference material for assessing a study's conclusions (Macdonald et al. 2000).

The objective of this paper is to describe, in detail, the full range of behavioural acts that we have observed in a captive group of five Eastern Coyotes. This ethogram is intended to be: (1) reader-friendly in format and applied and used in future direct observation behavioural studies of wild and captive Coyotes; and (2) compared with ethograms of closely related species (e.g., Wolves, Jackals [*Canis* sp.] and foxes) and taxa (e.g., ursids, procyonids, and mustelids: Ewer 1973).

Methods

On 12 April 2002, five (2 M; 3 F) of an original litter of nine (3 M; 6 F) estimated 25 day old (Parks 1979), wild-born sibling Coyote pups were removed from under a shed in a residential area in Falmouth (Cape Cod), Massachusetts, and were reared at JGW's house (note: the other four pups [1M; 3F] were placed back underneath the shed for the wild parents to raise). The five Coyotes taken into captivity were contained within a 53 m^2 area both inside and outside of JGW's house until 13 May 2002, when the Coyotes were transferred to a 16 m^2 quarantine facility for one month at the Franklin Park Zoo, Boston, Massachusetts. On 13 June 2002 the five Coyotes were moved to their permanent 403 m^2 public viewable exhibit at the Stone Zoo located in Stoneham, Massachusetts, and remained there for the duration of this study until late October 2003 – pup age 585 days). We chose the endpoint of our study as the last day of data collection prior to the Coyotes being permanently separated due to intrapack aggression (Late and Trans [See Table 1] were removed). The area of their exhibit was described by Frank (1987) as a suitable size for a long-term study of canid behaviour. Although the Coyotes were hand-raised, we made no attempt to interfere with or discipline their activities and therefore gave the Coyotes free access, at all times, to their exhibit/living facilities. The Coyotes were provided with puppy milk (Esbilac, PetAg, Inc., Hampshire, Illinois) via bottle or bowl up until 15 May and were given access to water and dry dog chow (commercially available dog foods until March 2003 then Mazuri exotic canine chow/diet [PMI Nutrition International, LLC., Brentwood, Missouri] thereafter) at all times. They were group fed (i.e., all five at once) 0.75 – 1.6 kg (varying with their age) of Nebraska Brand chopped frozen canine meat (Central Nebraska Packing Co., North Platte, Nebraska) mixed with dog chow on a daily basis and were given frozen or thawed laboratory rats, guinea pigs and mice (donated from a rodent breeding facility), and/or bones 2-4 times per week. Within their exhibit, the Coyotes commonly hunted (at least 1 prey item 2-3 times daily) and captured (about 1-2 prey items per week) Starlings (*Sturnus vulgaris*), House Sparrows (*Passer domesticus*), Chipmunks (*Tamias striatus*), Brown/Norway Rats (*Rattus norvegicus*), Meadow Voles (*Microtus pennsylvanicus*), and Gray Squirrels (*Sciurus carolinensis*), but did not appear to eat much or any of these prey items. Care and use of animal subjects was approved by Zoo New England's Institutional Animal Use and Care Committee (letter dated 23 January 2002 to JGW), by Boston College's Institutional Animal Care and Use Committee Protocol Number 01-03, and by the Massachusetts Division of Fisheries and Wildlife Permit #052. 02LP.

We developed an ethogram that noted basic behavioural patterns (Scott and Fuller 1965; Bekoff 1972a, 1972b, 1978; Parks 1979). To avoid influencing Coyote behaviour with different observers only JGW interacted with and conducted activity budgets on them. Using this technique, we acknowledge that we did not have interobserver reliability as described by Bekoff (1974) but the large amount of data collected attempted to offset intraobserver reliability. We used focal individual animal sampling (i.e., one Coyote per 30 min bout of data collection), took instantaneous point or scan samples (Martin and Bateson 1986; Macdonald et al. 2000) every 15 sec for 30 min on the target Coyote, recorded the date, time, and weather before each observation bout took place, and noted important contextual information in between each 15 sec sampling period. By using frequent (i.e., every 15 sec) instantaneous samples, we tried to obtain an accurate approximation from continuous recording (Martin and Bateson 1986). Thus, 120 samples per 30 min behavioural bout on a Coyote were ideally recovered. However, there were two reasons why we occasionally did not obtain 120 samples per bout: (1) a Coyote was momentarily out of sight during a particular 15 sec sampling period (usually this happened at most, once per 30 min bout); and (2) we had to stop a sampling bout earlier (e.g., rain, darkness, or some kind of disturbance that forced JGW to abandon an activity budget). We randomly chose which Coyote to conduct observations on before entering the field but attempted to evenly sample all Coyotes (i.e., each Coyote was scored every fifth time) during the study. We typically recorded behavioural data about 5 days/week and took between 1 and 4 (usually 1-2) 30 min behavioural bouts/day during daylight hours. Behaviours were also recorded on digital still and videocameras and 35-mm film cameras weekly for the duration of the juvenile period of the pups (Parks 1979) then *ad lib* after pups reached adulthood (one yr of age – Bekoff and Jamieson 1975). We conducted most of the behavioural bouts during early to mid-morning (ca. 07:00-11:00 h) or between late-afternoon to early-evening hours (ca. 16:00-19:30 h); these were the times with the fewest number of people around the zoo (the zoo opened at 10:00 and closed at 16:30-1800 h depending on the time of year). Because the Coyotes were habituated to and did not react negatively to JGWs presence, he followed them around the exhibit similar to the description of Goodall's (1986) "follows" of wild Chimpanzees (*Pan troglodytes*) in Gombe, Tanzania. JGW made an effort not to influence the movements and/or behaviour of Coyotes by minimizing his movement in the exhibit. This was especially important because the Coyotes would follow him around the exhibit when he interacted with them but would generally ignore him when he was standing erect and writing on a clipboard (J. Way, unpublished data). "Following" was a necessary technique to use on the Coyotes because there was not a single observation spot outside the exhibit where the Coyotes could reliably be seen all of the time (i.e., many times trees and shrubs concealed the Coyote under observa-

tion). Besides the senior author's presence, other human contact was kept to a minimum before and after each sampling period to avoid humans affecting Coyote behaviour. Context was a critical variable with respect to the Coyotes' response to human behaviour. For example, they generally ignored people (unless very loud) on the public path but would intently watch and/or bark at staff members that were behind (i.e., the opposite side of the public path that was off-limits to non-employees) or approaching their exhibit. Accordingly, zookeepers did not enter the exhibit to feed the Coyotes when JGW interacted with them. Despite these precautions there were no doubt many instances where Coyotes changed their activity in response to a person's (public or staff) presence – sometimes even when a person simply walked by their exhibit area. Similar instances of Coyotes shifting their behaviour because of the presence of people have been documented in areas where wild Coyotes inhabit urbanized areas (Way 2001). We attempted to mitigate these factors by increasing the total size of the pool of sample bouts.

We entered all of the data into an excel spreadsheet. First, we entered the raw data into the spreadsheet. Then we alphabetized that data in order to group similar behaviours for each budget. Next we summed the frequency of each distinct behaviour observed. Finally we entered those summed values into a separate file (for each Coyote) that had our developing ethogram. Due to the large amount of data and behaviour sequences in our ethogram (Table 1), properly entering and compiling data were critical parts of this ethogram's creation. Behavioural actions or patterns (denoted as subcategories in Table 1), as defined by Scott and Fuller (1965), were grouped into "parent" categories, or behavioural complexes as described by Schleidt et al. (1984), or behavioural systems, as noted by Scott and Fuller (1965), based on motivational context and activity observed (Parks 1979).

In our ethogram, we organized the categories and the behavioural actions within each of the complexes generally on a scale from less to more active or intense an activity, then from solitary to group-oriented activities. Notable exceptions were feeding, which was grouped next to hunting for obvious reasons, and self play, which was grouped close to social play but was of a solitary endeavor. The 16 parent categories that we believed best described and appropriately sorted the behavioural actions were resting, sitting, sitting1, sitting2, standing, traveling, explore/investigating, hunting, feeding, infantile, greeting, self play, play initiating, playing, agonistic, and miscellaneous. There were instances (especially early in our study when we were working on differentiating different behavioural actions) where a Coyote was engaged in an activity but we could not describe, other than in a general category, what the Coyote was doing. When this occurred (e.g., when a Coyote was behind trees and was only partially observed) we simply classified the behaviour in its parent category, so that we could at least provide a coarse description of a Coyote's behaviour at a given 15 sec interval (Table 1).

We calculated the percentage that each behaviour pattern was observed and added all within a parent category to examine the relative frequency that each behavioural complex/system occurred (Table 1). In addition, we used the ages (in days) of the Coyotes to denote the first time that each behaviour was observed, with day 27 (14 April 2002) being the beginning point – i.e., the date we first did an ethogram on a Coyote. We want to stress here that although we report both the percentage of each behaviour observed and the age that each behaviour was first recorded for comparison purposes (Table 1), the purpose of this manuscript is to describe the ethogram that we developed. We will more thoroughly analyze these data in future manuscripts.

Results and Discussion

The ethogram that we developed on the Eastern Coyote is presented as Table 1. A total of 72247 15-sec samples were taken amounting to 301 h of field time, varying between 59.4-61.3 h per Coyote. A total of 540 behavioural patterns were observed amongst the 16 behaviour categories ranging from 9 (Miscellaneous) to 72 (Explore and Investigate) acts per parent category (Table 1; Figures 1-25).

Resting (RE) occurred when a Coyote was lying down with its head on the ground. Sitting (SIT) was classified as sitting down either on rear or all four legs; this category was subsequently divided into sit1 (SIT1) and 2 (SIT2). SIT1 was noted when a Coyote was sitting down on all four legs; in other words, it was almost lying down but it had its head up. SIT2 was when a Coyote sat on its rear legs but its front legs were up in standing-like position. It was difficult to always reliably determine what the motivation was for a Coyote in the aforementioned positions. For example, a Coyote frequently sat in SIT1 position to sniff the ground. Because the animal was in a resting-like position we believed that it was important to separate these activities from explore/investigate activities where the animal was active (i.e., at least in a standing position). Similarly, it was sometimes difficult to understand the motivational context when an animal was just standing (ST) and performing routine activities. Thus, we developed a category for just standing activities.

Any of these categories could always be lumped together or put into different or new categories if the need arose – but the opposite cannot occur if the behaviours are not split into discrete actions at the outset (Bekoff 1972b). For example, SIT1 Alt and SIT1 Alt Pt were very similar except for the panting involved. Although we could have easily combined these categories we thought that keeping them separated would allow us to potentially analyze this difference in the future (e.g., the level of panting on hot versus cold days).

Resting and sitting behaviours were observed quite frequently and accounted for >23% of all of the ethogram despite the Coyotes generally being much more

TABLE 1. Ethogram on eastern Coyotes: "Age" refers to the age of the Coyotes (in days) when a behavior was first observed (data collection began on day 27 for Lupe and day 33 for others); "%" refers to the percentage of each behavioral pattern observed relative to the total number of samples (spot fixes) taken; a zero signifies that the behavior was either never recorded for a Coyote(s) or was <0.0049% (i.e., not rounded up to 0.01%); and letters in parentheses refer to abbreviations from the previous word(s) or phrase(s).

Parent Subcategory	Description	Age	%	Age					%

	Swat flies	Swatting bugs out of annoyance (e.g, not self play) while sitting	149	0.00	149	0	0	0	0	0.01	0.00	0.00	0.00	0.00
	Woof	Sit1 position and alertly making a warning woof-like call	85	0.00	0	0	85	0	0	0.00	0.00	0.01	0.00	0.00
SIT1	N = 54	Total percentage for SIT1:		11.96						10.89	9.10	9.14	17.73	12.78
SIT2		Sitting on back legs (rear haunches); front legs up in standing-like position	88	0.05	102	88	98	115	140	0.04	0.08	0.04	0.05	0.02
	Sniff	Sniffing in sit2 position	96	0.04	146	109	96	97	99	0.02	0.01	0.01	0.05	0.11
	Pant (pt)	Panting but not focused on anything (eyes open) while sitting	118	0.00	0	0	339	147	118	0.00	0.00	0.01	0.01	0.01
	Alt	Focused on something while sitting	96	0.67	96	105	100	97	97	0.31	0.64	0.59	0.71	1.12

	Alt pt	Same as above while panting	97	0.05	150	513	407	106	97	0.05	0.03	0.06	0.07	0.03
	Alt sn	Sniffing something (usually air) while alert in sit2 position	214	0.00	0	0	0	214	0	0.00	0.00	0.00	0.01	0.00
	I open	Sitting and not focused on anything but eyes open	102	0.00	102	0	0	0	0	0.02	0.00	0.00	0.00	0.00
	I open pt	Same as above while panting	551	0.00	0	551	0	0	0	0.00	0.01	0.00	0.00	0.00
	Lick self	Licking self while sitting	103	0.16	114	134	113	129	103	0.05	0.10	0.13	0.10	0.41
	Lick object	Licking an object while in sit2 position	99	0.01	102	0	0	99	0	0.01	0.00	0.00	0.02	0.00
	Move head	Quickly moving head while sitting	534	0.00	534	551	0	0	0	0.01	0.01	0.00	0.00	0.00
	Bite obj	Biting an object while sitting	97	0.00	0	0	0	99	97	0.00	0.00	0.00	0.01	0.01
	Chew obj	Chewing but not really feeding on something while sitting	99	0.08	146	388	110	120	99	0.05	0.01	0.16	0.13	0.04
	Scratch self	Scratch self; the typical dog-like scratch where a hindleg scratches the rib/shoulder region of body	45	0.13	135	45	108	99	103	0.16	0.08	0.13	0.11	0.18
	Look ar	Looking around; not focused on a specific object; sometimes exaggerated head movement	97	0.10	332	337	331	97	314	0.10	0.09	0.03	0.04	0.22
	Look ar pant	Same as above while panting	413	0.01	469	413	462	486	0	0.02	0.01	0.01	0.01	0.00
	Yawn	Yawning in sit2 position	267	0.01	0	267	311	376	311	0.00	0.01	0.02	0.01	0.01
	Whine	Whining; looking down; not focused on anything in particular	492	0.00	0	0	0	0	492	0.00	0.00	0.00	0.00	0.01
	Alt woof/bark	Giving a warning woof-like call/bark while sit2 position	304	0.00	0	0	304	0	0	0.00	0.00	0.01	0.00	0.00
	Howl	Howling in sit2 position	429	0.01	0	0	429	0	0	0.00	0.00	0.05	0.00	0.00
	Fake howl	Lifting head like howling but producing no sound	484	0.00	0	0	484	0	0	0.00	0.00	0.01	0.00	0.00
	Dig	Digging while in SIT2 position	519	0.00	0	0	0	519	0	0.00	0.00	0.00	0.01	0.00
	Sn dig	Sniffing and digging while in sit2 position	519	0.00	0	0	0	519	0	0.00	0.00	0.00	0.01	0.00
SIT2	N = 23	Total percentage for sit2:		1.34						0.84	1.09	1.25	1.35	2.16
Standing (ST)		Standing and performing behaviors that could not fit into other categories	33	0.42	33	34	34	34	33	0.43	0.33	0.44	0.48	0.45
	Doze	Dozing while in a standing position	301	0.00	0	0	0	0	301	0.00	0.00	0.00	0.00	0.01
	Eyes closed	Eyes closed while standing; often done in hot weather	344	0.00	0	344	0	0	0	0.00	0.01	0.00	0.00	0.00
	Eyes open	Eyes open but not focused on anything in particular while standing	361	0.00	361	0	0	0	396	0.01	0.00	0.00	0.00	0.01
	I open pt	Same as above while panting	479	0.00	0	479	497	0	0	0.00	0.01	0.01	0.00	0.00
	Pt I open hd down	Head facing down while standing and panting	466	0.00	0	0	466	0	0	0.00	0.00	0.01	0.00	0.00
	Blink	Blinking eyes while standing	301	0.01	0	0	0	0	301	0.00	0.00	0.00	0.00	0.03
	Yawn	Yawning while standing	174	0.07	272	267	177	174	234	0.06	0.15	0.06	0.04	0.06
	Yawn alt	Yawning while alert and standing	367	0.00	0	367	0	0	555	0.00	0.01	0.00	0.00	0.01
	Yawn wag tail	Yawning and wagging tail implying excitement	337	0.00	0	337	0	0	0	0.00	0.01	0.00	0.00	0.00
	Cough	Coughing while standing	78	0.01	0	149	561	531	78	0.00	0.01	0.01	0.01	0.01
	Pant (pt)	Panting but not really focusing on anything	94	0.01	0	380	108	102	94	0.00	0.01	0.01	0.01	0.04
	Alert (alt)	Focusing on something	34	7.70	38	37	40	34	39	8.57	8.76	5.08	7.50	8.58
	Alt pant	Alert while panting	92	0.75	114	92	100	102	94	0.52	0.95	0.95	0.42	0.92
	Alt wag tail	Wagging tail while alert, implying some level of excitement; usually around other Coyotes	54	0.14	171	170	528	54	304	0.14	0.20	0.04	0.29	0.06
	Alt wag tail pt	Same as above while panting	427	0.02	427	427	0	531	575	0.01	0.01	0.00	0.05	0.01
	Alt pt tail up	Tail high while standing alert and panting	297	0.00	0	0	0	0	297	0.00	0.00	0.00	0.00	0.01
	Alt tail tucked	Standing alert with tail tucked between legs; sign of submissiveness	582	0.00	0	582	0	0	0	0.00	0.01	0.00	0.00	0.00
	Alt whine	Focused on something and whining	316	0.01	0	0	316	0	0	0.00	0.00	0.03	0.00	0.00

TABLE 1. Ethogram on eastern Coyotes *(continued)*

Parent Subcategory	Description	Age	%	Age					%				
		All 5	All 5	Cane	Caon	Late	Lupe	Trans	Cane	Caon	Late	Lupe	Trans
Alt whine wag tail	Same as above while wagging tail; Coyote appears anxious; socially related	380	0.00	0	380	0	0	0	0.00	0.01	0.00	0.00	0.00
Lick self	Grooming licking self	55	0.60	111	62	78	70	55	0.43	0.92	0.47	0.61	0.57
Lick coy	Briefly licking another Coyote but not grooming so not infantile behaviour	72	0.01	527	399	72	299	285	0.01	0.01	0.01	0.01	0.03
Lick object	Licking an object while standing	65	0.11	65	156	98	186	123	0.06	0.03	0.03	0.30	0.14
Chew obj	Chewing an object while standing	44	2.78	47	47	47	58	44	2.24	2.33	2.93	2.83	3.59
Chew alt	Same as above while alert	122	0.01	177	290	122	0	0	0.01	0.01	0.01	0.00	0.00
Chew wag tail	Chewing something while wagging tail; excitement evident	430	0.00	430	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Bite obj	Bite at an object, like a branch, while standing	43	0.48	50	45	67	43	45	0.44	0.49	0.35	0.51	0.60
Bite obj hind legs	Bite at an object while standing on hindlegs	147	0.01	0	147	0	0	0	0.00	0.03	0.00	0.00	0.00
Hind legs bite coy	Making general (not Ag) bites at another Coyote while standing on hindlegs	390	0.00	0	390	0	0	0	0.00	0.01	0.00	0.00	0.00
Stretch	Stretching body while standing	59	0.14	59	136	128	77	62	0.07	0.04	0.18	0.29	0.09
Alt & stretch	Same as above while alert	94	0.00	0	0	0	0	94	0.00	0.00	0.00	0.00	0.01
Stretch yawn	Yawning while stretching	177	0.01	214	0	177	303	0	0.01	0.00	0.03	0.01	0.00
Stretch urinate	Stretching and squat-urinating at same time while standing	367	0.00	0	0	0	367	0	0.00	0.00	0.00	0.01	0.00
Rub body	Rubbing body against an object (fence, tree) in standing position	81	0.18	126	153	134	97	81	0.03	0.09	0.31	0.20	0.25
Scratch	Scratching self while standing	45	0.02	379	453	134	67	45	0.03	0.04	0.01	0.02	0.02
Shake body	Shaking body – to dry or get dust off self	37	0.12	38	37	43	45	39	0.13	0.11	0.11	0.12	0.14
Shake head	Twist or shake just the head and neck	149	0.04	527	528	429	295	149	0.03	0.07	0.06	0.03	0.02
Paw object	Pawing at something halfheartedly; not really investigating	142	0.00	0	0	0	142	0	0.00	0.00	0.00	0.02	0.00
Hold object	Holding something in mouth while standing	111	0.02	111	143	122	138	136	0.01	0.01	0.02	0.03	0.01
Drop object	Releasing an object from mouth while standing	338	0.00	0	0	0	499	338	0.00	0.00	0.00	0.01	0.01
Defecate	Defecating, in a squatting position	37	0.12	44	43	38	37	65	0.16	0.15	0.10	0.08	0.11
St b/r	General term for going to bathroom; then divided into urinate and defecate	35	0.01	35	45	44	52	0	0.01	0.01	0.03	0.02	0.00
Urinate	Urinating by leaning forward or standing	34	0.12	38	37	40	34	39	0.10	0.07	0.04	0.22	0.17
FLU	Flex leg urination; flexing forward and partially lifting a hindleg	499	0.02	527	499	512	531	505	0.02	0.04	0.02	0.01	0.01
RLU	Raised leg urination; lifting a hindleg	303	0.00	0	0	0	303	0	0.00	0.00	0.00	0.02	0.00
Alt hindlegs	Standing alert while on hindlegs (looking like a standing human)	58	0.03	430	73	64	58	112	0.01	0.03	0.02	0.07	0.01
Over others	Standing over another Coyote but not really looking at anything; no aggression seen – head alertness not noted	34	0.09	39	34	49	38	185	0.29	0.06	0.01	0.07	0.03
Over others alt	Same as above while focused on something	317	0.04	317	525	402	0	0	0.20	0.01	0.01	0.00	0.00
Over alt pt	Same as above while panting	512	0.00	0	518	512	0	0	0.00	0.01	0.01	0.00	0.00
Over coy hd down	Same as above while head is down (not focused on anything)	534	0.00	534	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Over coy head down pt	Same as above while panting	464	0.01	0	464	512	0	0	0.00	0.01	0.01	0.00	0.00
Over coy look ar	Same as above while looking around	498	0.01	498	0	0	0	0	0.03	0.00	0.00	0.00	0.00
Alt body low wag tail	Standing alert with body low while wagging tail; nervous behaviour of submissive Coyotes	380	0.00	0	380	0	0	0	0.00	0.01	0.00	0.00	0.00
Vomit	Convulsing/throw up while standing	110	0.03	126	0	0	115	110	0.05	0.00	0.00	0.03	0.05

	Sneeze	Sneezing in a standing position	225	0.00	443	0	225	0	532	0.01	0.00	0.01	0.00	0.01
	Whine	Whining; not really looking around but eyes open	34	0.23	35	34	34	34	35	0.13	0.11	0.38	0.43	0.11
	Bark/woof	Woof-barking (warning call) at something (usually a person)	27	0.03	0	420	185	27	59	0.00	0.06	0.06	0.02	0.01
	Alt bark/woof	Same as above while alert	225	0.03	0	569	225	236	0	0.00	0.01	0.15	0.01	0.00
	Howl alone	Lone howl while standing	33	0.07	35	34	34	34	33	0.01	0.16	0.17	0.01	0.03
	Bark howl	Bark howl while standing	38	0.00	38	0	417	0	0	0.01	0.00	0.01	0.00	0.00
	Howl & whine	Howling and whining while standing	38	0.00	0	0	38	0	0	0.00	0.00	0.01	0.00	0.00
	Howl group	Group howl while standing	34	0.02	0	390	417	34	401	0.00	0.04	0.02	0.03	0.02
	Fake howl	Going through howling motion but no sound produced	44	0.02	0	44	423	0	0	0.00	0.07	0.06	0.00	0.00
	Step	Stepping to one side with front legs	548	0.01	559	562	0	548	549	0.01	0.01	0.00	0.02	0.01
	Step alt	Same as above but while alert – usually done to get a better view	547	0.01	0	547	561	0	0	0.00	0.03	0.01	0.00	0.00
ST	N = 67	Total percentage for St:		14.62						14.28	15.53	12.28	14.83	16.21
Traveling (T)		Traveling; moving with purpose from point A to B	27	0.74	35	34	34	27	33	0.67	0.44	0.82	0.73	1.03
	Walk (Wk)	Walking – slow movement when lateral legs move together; two legs always on the ground	43	2.42	75	48	43	51	68	3.16	2.29	2.01	2.45	2.19
	Wk pant (pt)	Walking and panting	106	0.24	117	112	119	106	107	0.25	0.23	0.12	0.22	0.41
	Wk alt	Walking and focused on something ahead	47	2.70	93	105	71	73	47	3.17	2.77	2.47	1.98	3.12
	Wk alt pt	Same as above while panting	94	0.21	98	194	181	148	94	0.20	0.17	0.15	0.16	0.36
	Wk wag tail	Walking and wagging tail; looks excited – almost greet SuA	170	0.02	302	170	0	0	540	0.03	0.06	0.00	0.00	0.01
	Wk alt wag tail	Same as above while alert	214	0.01	214	344	402	0	311	0.02	0.01	0.01	0.00	0.02

	Wk chew obj	Walking and chewing on something	122	0.03	122	143	132	142	143	0.04	0.02	0.07	0.03	0.01
	Wk drag obj	Walking and dragging a large object like a branch	47	0.01	0	50	47	0	0	0.00	0.02	0.02	0.00	0.00
	Wk scratch/rub	Walking and rubbing body against object (fence, branch)	316	0.00	0	0	316	0	0	0.00	0.00	0.01	0.00	0.00
	Wk stretch	Walking and stretching	133	0.00	0	0	0	133	0	0.00	0.00	0.00	0.01	0.00
	Wk wh wag tail	Walking and whining while wagging tail; nervous	365	0.00	0	0	365	0	0	0.00	0.00	0.01	0.00	0.00
	Wk wag body	Walking and wagging body; very excited but not directed at a Coyote	373	0.00	0	373	0	0	0	0.00	0.01	0.00	0.00	0.00
	Wk shake self	Walking and shaking body; usually done when wet	132	0.01	294	0	132	295	297	0.01	0.00	0.02	0.01	0.01
	Wk body low	Walking with body low; done by submissive Coyotes	362	0.02	0	362	386	0	0	0.00	0.06	0.02	0.00	0.00
	Wk bod low wg tl	Walking with body low and wagging tail SuA like but done to no Coyote	375	0.00	0	375	0	0	0	0.00	0.01	0.00	0.00	0.00
	Wk limp	Limping while walking	45	0.00	0	45	0	0	0	0.00	0.01	0.00	0.00	0.00
	Wk yawn	Walking and yawning	147	0.02	390	147	522	186	268	0.01	0.04	0.01	0.01	0.03
	A wk	Approaching a Coyote or human while walking	34	0.02	541	506	34	109	92	0.01	0.02	0.04	0.03	0.02
	Wk follow	Walking while purposely following another Coyote(s)	99	0.06	332	275	346	99	241	0.03	0.06	0.09	0.07	0.06
	Wk defecate	Defecating while walking	518	0.00	0	0	518	0	0	0.00	0.00	0.01	0.00	0.00

TABLE 1. Ethogram on eastern Coyotes *(continued)*

Parent Subcategory	Description	Age	%	Age					%				
		All 5	All 5	Cane	Caon	Late	Lupe	Trans	Cane	Caon	Late	Lupe	Trans
A wk limp	Approaching a Coyote while walking with a limp	43	0.00	0	43	0	0	0	0.00	0.01	0.00	0.00	0.00
Trot	Trotting while looking down; not focused on anything; going the equivalent of jogging pace for humans (includes loping and cantering) where left front and right rear legs touch ground at same time, and vice versa	48	1.84	80	77	48	80	48	1.93	2.18	1.61	1.28	2.21
Trot pt	Trotting and panting while looking down	107	0.14	122	174	119	135	107	0.10	0.16	0.18	0.11	0.14
Trot alt	Trotting and focused on something	88	1.49	135	124	88	135	129	1.89	1.33	1.70	0.87	1.69
Trot alt pant	Same as above while panting	394	0.12	413	469	417	410	394	0.07	0.03	0.27	0.05	0.18
Trot tail high	Trotting with tail high; done by a confident, more dominant Coyote	236	0.00	236	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Trot alt tail high	Same as above while alert	250	0.00	0	250	0	0	0	0.00	0.01	0.00	0.00	0.00
Trot wag tail	Wagging tail while trotting; sign of excitement	257	0.01	0	257	0	0	0	0.00	0.03	0.00	0.00	0.00
Trot alt wag tail	Trotting and alert while wagging tail	375	0.01	469	375	550	0	0	0.01	0.01	0.01	0.00	0.00
Trot pt wag tail	Trotting and panting while wagging tail	453	0.00	0	453	0	0	0	0.00	0.01	0.00	0.00	0.00
Trot whine	Trotting and whining; clearly anxious about something	344	0.01	0	344	374	0	0	0.00	0.01	0.02	0.00	0.00
Trot alt whine	Trotting alertly while whining	379	0.00	0	0	379	0	0	0.00	0.00	0.02	0.00	0.00
Trot alt woof	Trotting alertly while barking at something, usually human	235	0.02	0	536	235	341	338	0.00	0.01	0.06	0.01	0.01
Trot tail low	Trotting with tail low; social implications (subordination)	373	0.00	0	373	0	0	0	0.00	0.01	0.00	0.00	0.00
Trot body low	Trotting with whole body low; social subordination	44	0.01	44	373	462	0	44	0.01	0.05	0.01	0.00	0.01
Trot yawn	Trotting and yawning	365	0.00	452	0	365	0	429	0.01	0.00	0.01	0.00	0.01
Trot with obj	Trotting with object in mouth	126	0.06	145	156	150	126	136	0.07	0.04	0.11	0.04	0.03
Gr trot	Trotting as a group (with ≥2 others) from one place to another	109	0.02	236	448	365	109	170	0.02	0.01	0.01	0.01	0.03
Trot follow	Trotting and following other Coyote(s)	59	0.11	59	124	74	97	107	0.04	0.08	0.17	0.07	0.19
Trot follow coy pt	Same as above while panting	469	0.01	469	0	497	0	527	0.01	0.00	0.02	0.00	0.02
Trot follow me	Following JGW at a trot while he moves	59	0.00	0	59	0	0	0	0.00	0.01	0.00	0.00	0.00
A trot	Approach human (JGW) or Coyote at a trot	27	0.59	38	34	39	27	33	0.67	0.70	0.49	0.45	0.63
A trot gr	Approach group at a trot	221	0.00	0	221	0	221	0	0.00	0.01	0.00	0.01	0.00
Run	Moving at a fast pace; body stretched out; not focused on anything; all four legs often in the air	33	0.33	33	45	44	44	45	0.39	0.32	0.43	0.22	0.29
Run alt	Running while alert – focused on something	165	0.03	294	167	235	193	165	0.03	0.01	0.07	0.01	0.05
Run alt pt	Running while alert and panting	423	0.00	0	0	423	0	0	0.00	0.00	0.01	0.00	0.00
Run alt woof	Running and alert while barking at something	341	0.00	0	0	0	341	0	0.00	0.00	0.00	0.01	0.00
Run with obj	Running with object in mouth	194	0.00	0	194	0	0	0	0.00	0.01	0.00	0.00	0.00
Run howl	Running and howling at same time	362	0.00	0	0	0	362	0	0.00	0.00	0.00	0.01	0.00
Run body low	Running with body low; social subordination	344	0.00	0	344	0	0	0	0.00	0.01	0.00	0.00	0.00
Run tail tucked	Running with tail tucked; social subordination	181	0.00	0	413	181	0	0	0.00	0.01	0.01	0.00	0.00
Run follow	Running while following another Coyote(s); no interactions taking place with that Coyote	47	0.01	340	0	105	0	47	0.01	0.00	0.02	0.00	0.02
A run	Approaching something at a run	91	0.01	0	0	167	91	285	0.00	0.00	0.01	0.01	0.01
Flee	Reflex-like response of running away from something	73	0.00	0	0	0	73	0	0.00	0.00	0.00	0.01	0.00

T	N = 63	Total percentage for T:		11.50					12.99	11.32	11.32	9.02	12.85
Export/Investigate (E/I)		Exploring/investigating surroundings; moving in a non-direct manner	27	7.10	33	34	34	27	33	7.69	6.12	6.78	7.76	7.13
	Pt	General e/i behaviour while panting	94	0.00	0	0	0	0	94	0.00	0.00	0.00	0.00	0.01
	Stand (st) sn	Standing and sniffing something (ground, tree, branch)	33	8.12	49	37	51	34	33	8.83	7.86	7.98	7.11	8.85
	St sn & alt	Standing and sniffing (usually the air) something while alert	34	0.02	120	0	128	34	118	0.05	0.00	0.01	0.01	0.01
	St sn pt	Standing and sniffing something while panting	151	0.01	0	0	0	486	151	0.00	0.00	0.00	0.01	0.03
	St sn stretch	Standing and sniffing something while stretching	172	0.00	0	0	0	172	0	0.00	0.00	0.00	0.01	0.00
	St sn wag tail	Standing and sniffing while wagging tail; excitement indicated	214	0.01	214	518	0	548	486	0.01	0.01	0.00	0.01	0.01
	St sn urinate	Standing and sniffing while urinating	82	0.00	0	257	0	82	0	0.00	0.01	0.00	0.01	0.00
	St sn whine	Standing and sniffing while whining (anxiety)	397	0.00	0	0	397	0	0	0.00	0.00	0.01	0.00	0.00
	St sn Coyote	Standing and sniffing another Coyote	80	0.15	80	96	132	82	123	0.14	0.22	0.09	0.19	0.11
	St sn (me)	Standing and sniffing JGW	227	0.00	0	227	0	0	0	0.00	0.01	0.00	0.00	0.00
	St sn gr	Standing and sniffing as a group	88	0.01	181	127	88	178	110	0.01	0.01	0.03	0.01	0.01
	St sn & bite	Standing and sniffing something while biting an object	121	0.01	0	121	122	0	129	0.00	0.01	0.03	0.00	0.01
	St sn & chew	Standing and sniffing something while chewing on an object	85	0.02	85	0	0	537	0	0.07	0.00	0.00	0.02	0.00
	St sn & pull at	Standing and sniffing something while pulling on an object	142	0.00	142	0	0	0	0	0.01	0.00	0.00	0.00	0.00
	Hind legs	Investigate something on hind legs	59	0.10	60	64	59	62	59	0.10	0.06	0.09	0.09	0.16
	Sn hind legs	Sniff something on hind legs	52	0.05	52	62	59	53	123	0.05	0.06	0.01	0.05	0.06
	Look around (ar)	Looking around; usually standing but sometimes involves moving around (stepping) slowly from side-to-side	34	2.46	42	53	81	34	59	3.13	2.13	2.09	2.20	2.77
	Look ar pant	Same as above while panting	406	0.53	413	413	407	410	406	0.31	0.49	0.94	0.39	0.54
	Look ar tail up	Looking around with tail up; a sign of dominance	528	0.00	0	0	528	0	0	0.00	0.00	0.01	0.00	0.00
	Look ar wag tail	Same as above while wagging tail	318	0.04	413	453	550	318	532	0.03	0.05	0.01	0.07	0.04
	Look ar wag tail pt	Looking around while wagging tail and panting	413	0.01	0	413	0	519	0	0.00	0.01	0.00	0.04	0.00
	Look ar sneeze	Looking around and sneezing	541	0.00	0	0	541	0	0	0.00	0.00	0.01	0.00	0.00
	Look ar whine	Looking around and whining	518	0.01	0	0	518	0	0	0.00	0.00	0.03	0.00	0.00
	Step sn	Stepping to side with front legs while sniffing; formerly classified as wk sn but documented more often after this study	564	0.00	564	0	0	0	0	0.01	0.00	0.00	0.00	0.00
	Walk (wk) around	Walking around with no apparent direction in mind; usually looking at different things while walking	59	5.23	59	85	60	70	59	5.07	6.79	6.34	3.68	4.30
	Wk ar pant	Same as above while panting	339	0.79	413	413	339	410	410	0.59	1.23	1.01	0.48	0.67
	Wk ar yawn	Same as above while panting	499	0.00	0	499	0	0	0	0.00	0.01	0.00	0.00	0.00
	Wk ar wag tail	Walking around and wagging tail indicating excitement	302	0.08	302	344	379	414	483	0.07	0.22	0.04	0.02	0.04
	Wk ar pt wag tail	Same as above while panting	469	0.01	0	469	0	531	0	0.00	0.01	0.00	0.02	0.00
	Wk ar body low	Walking around with body low; social subordination	399	0.01	0	399	451	0	0	0.00	0.06	0.01	0.00	0.00
	Wk ar limp	Walking around and limping on a leg	43	0.00	0	43	0	0	0	0.00	0.01	0.00	0.00	0.00
	Wk ar whine	Walking around while whining; implying anxiousness	339	0.02	0	413	339	0	0	0.00	0.01	0.07	0.00	0.00
	Wk ar whin tl high	Walking around while whining but tail high; confusion apparent where Coyote whines but has tail up indicating confidence	518	0.00	0	0	518	0	0	0.00	0.00	0.01	0.00	0.00
	Wk ar & woof	Walk around and make warning calls	368	0.00	0	431	368	0	0	0.00	0.01	0.01	0.00	0.00
	Wk and look ar	Exaggerated movements of looking everywhere while walking around.	94	0.05	120	131	141	526	94	0.01	0.04	0.01	0.02	0.15

TABLE 1. Ethogram on eastern Coyotes *(continued)*

Parent Subcategory	Description	Age	%	Age					%				
		All 5	All 5	Cane	Caon	Late	Lupe	Trans	Cane	Caon	Late	Lupe	Trans
Wk ar group (gr)	Walking around in a group (>2 others) setting; social interactions implied but nothing specific happening	281	0.02	281	479	484	0	0	0.01	0.04	0.05	0.00	0.00
Wk sn	Walking and sniffing the ground	82	4.20	98	109	88	82	87	3.40	4.50	5.95	3.19	4.03
Wk sn Coyote	Walking and sniffing another Coyote	508	0.00	0	547	0	0	508	0.00	0.01	0.00	0.00	0.01
Wk sn pt	Walking and sniffing while panting	464	0.01	469	464	466	0	0	0.01	0.01	0.04	0.00	0.00
Wk sn wag tail	Same as above while wagging tail (excitement)	408	0.00	408	0	550	0	0	0.01	0.00	0.01	0.00	0.00
Wk sn whine	Same as above while whining (anxious)	368	0.01	0	0	368	0	0	0.00	0.00	0.03	0.00	0.00
Wk sn gr	Walking in sniffing with (≥2 others	103	0.00	0	0	0	0	103	0.00	0.00	0.00	0.00	0.01
Trot around (ar)	Trotting around with no apparent direction	129	0.88	257	227	144	295	129	0.65	1.14	1.72	0.33	0.60
Trot ar pant	Same as above while panting	406	0.19	463	413	417	410	406	0.05	0.08	0.68	0.03	0.14
Trot ar tail low	Same as above with tail low; submissiveness indicated	420	0.00	0	420	0	0	0	0.00	0.01	0.00	0.00	0.00
Trot ar tail tucked	Same as above with tail tucked; submissiveness indicated	582	0.00	0	582	0	0	0	0.00	0.01	0.00	0.00	0.00
Trot ar pt tail high	Same as above with tail high; dominance indicated	545	0.00	0	0	545	0	0	0.00	0.00	0.01	0.00	0.00
Trot ar wh tl high	Trotting around while whining but tail high; confusion apparent where Coyote whines but has tail up indicating confidence	518	0.00	0	0	518	0	0	0.00	0.00	0.01	0.00	0.00
Trot ar wag tail	Same as above while wagging tail	344	0.03	413	344	545	0	532	0.03	0.11	0.01	0.00	0.01
Trot ar wg tail eee	Same as above while making the shreel-like sound	544	0.00	544	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Trot ar body low	Same as above with body low	399	0.01	0	399	0	0	0	0.00	0.06	0.00	0.00	0.00
Trot ar whine	Trotting around while whining	411	0.02	0	0	411	0	0	0.00	0.00	0.08	0.00	0.00
Trot ar pt whine	Same as above while panting	477	0.00	0	0	477	0	0	0.00	0.00	0.01	0.00	0.00
Trot sn	Trotting and sniffing ground	125	0.21	162	141	125	178	148	0.07	0.11	0.66	0.02	0.19
Trot sn pant	Trotting and sniffing while panting	417	0.00	0	0	417	0	0	0.00	0.00	0.01	0.00	0.00
Trot sn whine	Trotting and sniffing while whining	541	0.00	0	0	541	0	0	0.00	0.00	0.01	0.00	0.00
Run around	Running around; random cutting and zigzagging across exhibit	411	0.02	0	0	411	0	505	0.00	0.00	0.06	0.00	0.01
Run ar pt	Running around and panting	477	0.00	0	0	477	0	0	0.00	0.00	0.01	0.00	0.00
Run sniff	Running and sniffing the ground	423	0.00	0	0	423	0	0	0.00	0.00	0.01	0.00	0.00
Circling	Moving around in a circular motion	65	0.00	65	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Dig/paw	Digging or pawing at an object; very active with paws	34	0.33	44	42	38	34	35	0.22	0.40	0.55	0.31	0.15
Paw on hind legs	Same as above on hind legs	59	0.00	0	0	0	59	0	0.00	0.00	0.00	0.01	0.00
Dig pt	Same as above while panting	466	0.00	0	0	466	0	0	0.00	0.00	0.01	0.00	0.00
Dig/paw sniff	Same as above while sniffing standing or crouched (forelegs low)	91	0.28	117	105	93	91	118	0.31	0.28	0.34	0.37	0.11
Dig & bite	Dig and bite at an object (e.g., roots)	96	0.01	96	0	0	0	0	0.04	0.00	0.00	0.00	0.00
Dig & chew	Dig and chew on an object (e.g., sticks)	125	0.01	0	0	125	0	0	0.00	0.00	0.03	0.00	0.00
Cache	Burying an object (e.g., carcass) usually using nose to push dirt over object	39	0.03	49	0	39	341	0	0.03	0.00	0.04	0.06	0.00
Cache & whine	Same as above while whining	39	0.00	0	0	39	0	0	0.00	0.00	0.01	0.00	0.00
Push obj	Pushing an object with feet or nose	367	0.00	0	0	0	367	0	0.00	0.00	0.00	0.01	0.00
Pull obj	Pulling/dragging (walking backwards) something like a branch	47	0.07	68	62	47	58	0	0.06	0.10	0.03	0.16	0.00
Whine	General exploring behavior while whining; indicting anxious/nervousness	39	0.01	0	53	43	39	0	0.00	0.01	0.01	0.02	0.00

E&I	N = 72	Total percentage for E/I:		32.23					31.07	32.30	36.0	26.71	30.18
Hunting (HU)		Hunting behavior; actively trying to catch or kill an object; it was difficult to distinguish between a Coyote's behavior/intentions/body language when hunting mice or stalking conspecifics so they are merged together	49	0.02	59	73	122	237	49	0.02	0.01	0.01	0.01	0.04
	Dig/paw	Pawing/batting (with paw) at something like a mouse	241	0.01	261	0	277	0	241	0.01	0.00	0.01	0.00	0.05
	Paw stab	Trying to stab something with quick paw movements	260	0.01	0	0	260	367	382	0.00	0.00	0.01	0.01	0.01
	Bite (air)	Biting air while typically trying to catch birds in flight	106	0.00	0	0	277	106	0	0.00	0.00	0.01	0.01	0.00
	Jump	Jumping at prey, mostly birds in flight	228	0.00	0	0	270	0	228	0.00	0.00	0.01	0.00	0.01
	Pounce	Jumping up and landing on prey (e.g., mousing)	176	0.01	261	0	198	0	176	0.01	0.00	0.01	0.00	0.02
	Ambush-crouch sit1	Intently watching Coyote or prey while hiding in sit1 Alt position (body near ground); body tense; ears pricked forward, eyes locked on target	469	0.00	469	0	0	0	0	0.01	0.00	0.00	0.00	0.00
	Amb-cr sit2	Same as above but in sit2 position	391	0.00	0	0	0	391	532	0.00	0.00	0.00	0.01	0.01
	Ambush-crouch St	Same as above but in a standing position	40	0.10	40	48	51	102	48	0.06	0.08	0.19	0.06	0.08
	Ambush-stalk	Creeping up on a Coyote or prey; body still very tense; ears pricked forward	39	0.24	39	43	51	58	43	0.26	0.18	0.24	0.11	0.42
	Ambush-rush	Running towards prey/Coyote; context not always clear when after a Coyote (e.g., initiating play, practicing hunting, disciplining other)	39	0.04	39	40	125	178	43	0.02	0.04	0.01	0.10	0.05
	Chase (prey)	Full speed chase to catch prey	106	0.10	226	167	213	106	170	0.10	0.05	0.06	0.07	0.20
	N = 12	Total percentage for HU:		0.53						0.48	0.36	0.55	0.38	0.89
Feeding (FE)		Feeding; ingesting something	27	1.16	33	34	34	27	39	1.03	1.19	1.15	1.39	1.05
	Alt	Standing alert while feeding; usually while standing	129	0.00	0	0	0	0	129	0.00	0.00	0.00	0.00	0.01
	Sit1	Feeding while in sit1 position	77	0.00	0	0	0	77	0	0.00	0.00	0.00	0.01	0.00
	Grass	Eating grass - standing	35	0.14	35	39	40	42	52	0.13	0.11	0.13	0.18	0.14
	Grass sit1	Eating grass – in sit1	54	0.00	54	0	0	97	0	0.01	0.00	0.00	0.01	0.00
	Dog chow	Eating dog food (dry chow); usually while standing	33	0.59	33	50	48	60	65	0.53	0.45	0.99	0.43	0.53
	Meat	Eating meat (supplied by zookeepers); usually while standing	33	0.03	33	194	0	34	39	0.10	0.01	0.00	0.01	0.01
	Carcass	Eating a rat or guinea pig or something they killed; this is most often in sit1	33	0.01	33	42	0	51	0	0.03	0.01	0.00	0.01	0.00
	Bone	Eating a bone – usually the fat on the bone	39	0.13	52	53	48	39	48	0.16	0.06	0.03	0.20	0.18
	Ice	Chewing and eating ice	177	0.01	177	0	0	0	0	0.03	0.00	0.00	0.00	0.00
	Drink	Drinking water; usually while standing	40	0.46	64	40	59	67	44	0.35	0.32	0.85	0.38	0.41
	Misc	Ingesting something (undetermined)	37	0.16	47	37	43	39	39	0.14	0.21	0.08	0.10	0.27
	T walk	Eating (usually dry dog food) while walking	39	0.04	39	47	86	39	79	0.03	0.09	0.01	0.03	0.05
	T run	Eating (usually dry dog food) while running	78	0.00	0	0	78	0	0	0.00	0.00	0.01	0.00	0.00
	N = 14	Total percentage for FE:		2.72						2.53	2.44	3.24	2.75	2.65
Infantile (IN)		Infantile; neonatal (close body) contact and/or licking/ grooming (non-face areas) ≥ 1 other Coyotes	27	0.50	38	37	40	27	39	0.63	0.56	0.34	0.75	0.22
	Resting	Re position on each other clearly for close contact; not really looking at anything; typically was done during rain	37	0.28	50	48	59	37	59	0.31	0.27	0.28	0.17	0.38
	Re sleep	Same as above while sleeping	59	0.01	0	59	0	0	0	0.00	0.03	0.00	0.00	0.00
	Sit1	Same as above but in sit1	119	0.01	0	131	119	0	338	0.00	0.02	0.01	0.00	0.01

TABLE 1. Ethogram on eastern Coyotes *(continued)*

Parent Subcategory	Description	Age	%	Age					%				
		All 5	All 5	Cane	Caon	Late	Lupe	Trans	Cane	Caon	Late	Lupe	Trans
Sit2	Same as above but in sit2	168	0.01	168	0	0	0	0	0.03	0.00	0.00	0.00	0.00
Stand (St)	Same as above but standing	38	0.02	38	0	368	0	73	0.10	0.00	0.01	0.00	0.01

St sn Coyote	Same as above but while sniffing another Coyote	66	0.00	0	66	0	0	0	0.00	0.01	0.00	0.00	0.00
Lick coy	Licking another Coyote while standing up	38	0.21	59	43	43	38	44	0.22	0.29	0.10	0.39	0.04
Lick sit	Same as above but sitting (sit1 or 2 not noted)	85	0.00	0	0	0	85	0	0.00	0.00	0.00	0.01	0.00
Lick sit1	Licking another Coyote while in sit1 position	123	0.07	544	362	0	123	185	0.01	0.06	0.00	0.29	0.01
Lick sit2	Same as above but in sit2	168	0.00	168	0	0	0	0	0.02	0.00	0.00	0.00	0.00
Licked	Getting licked by another Coyote usually standing but sometimes in sit1 position (i.e., position not noted)	133	0.07	168	212	368	133	140	0.07	0.06	0.22	0.01	0.01
Licked sit2	Getting licked by another Coyote while in sit2 position	492	0.00	0	0	0	0	492	0.00	0.00	0.00	0.00	0.01
Licked & wag tail	Same as above but wagging tail	525	0.00	0	525	0	0	0	0.00	0.01	0.00	0.00	0.00
N = 16	Total percentage for IN:		1.20						1.41	1.31	0.96	1.62	0.69
Greet GR)	Neutral to positive social contacts where licking face and muzzle touching occurred; tail wagging is common; characterized by non-agonistic and non-play encounters	34	0.02	39	34	77	39	0	0.03	0.02	0.01	0.03	0.00
Coyote st (coy)	Greeting a Coyote as mentioned above while standing	34	0.53	64	34	34	34	121	0.56	0.70	0.68	0.42	0.30
Coy sit1	Greeting a Coyote as mentioned above while sitting1	72	0.05	146	233	132	72	94	0.03	0.01	0.03	0.13	0.04
Coy sit2	Greeting a Coyote as mentioned above while sitting2	230	0.00	0	0	230	0	555	0.00	0.00	0.01	0.00	0.01
Coy moving	Greeting a Coyote while moving (walking)	185	0.01	498	215	185	362	0	0.01	0.01	0.01	0.01	0.00
Person	Greeting a person (JGW) with the same body movements and behavior	34	0.53	38	34	34	34	35	0.39	0.72	0.49	0.64	0.40
me sit	Greeting a person (JGW) while Coyote is sitting	70	0.00	0	0	0	70	0	0.00	0.00	0.00	0.01	0.00
Me sit2	Greeting a person (JGW) while Coyote is in sit2 position	514	0.00	0	0	0	514	0	0.00	0.00	0.00	0.01	0.00
Me on hindlegs	Greeting a person (JGW) while Coyote is on hindlegs – forelegs up on chest	548	0.00	0	0	0	548	0	0.00	0.00	0.00	0.01	0.00
Person & whine	Greeting a person (JGW) while Coyote is whining	34	0.01	44	34	0	0	0	0.01	0.01	0.00	0.00	0.00
Coy & person	Greeting both people and Coyote(s)	390	0.00	390	0	0	0	0	0.01	0.00	0.00	0.00	0.00
SuA	Active submission where one Coyote comes by in a low (submissive) posture and licks another's muzzle; exaggerated tail wagging is common	33	0.14	33	45	144	115	35	0.14	0.48	0.05	0.01	0.05
SuA group	Where a Coyote does SuA to the group (≥2 others)	134	0.03	544	134	323	0	0	0.01	0.13	0.01	0.00	0.00
SuA whine	Where a Coyote does SuA and whines to another	263	0.00	0	0	263	0	0	0.00	0.00	0.02	0.00	0.00
N = 14	Total percentage for GR:		1.33						1.19	2.08	1.31	1.26	0.81
Play Self (PS)	Self play incorporating many concepts of play; movements are exaggerated and random, wide-eyes, jaws open, lips retracted (play face), appears pleasurable	27	0.84	33	39	38	27	35	0.78	0.58	1.47	0.90	0.49
Gm	General movements such as walking around, moving head and eyes;												

	erratic, clearly having fun	49	0.00	0	0	49	0	0	0.00	0.00	0.01	0.00	0.00
Chase tail	Chasing own tail	55	0.01	498	55	80	0	148	0.01	0.03	0.01	0.00	0.01
head shake	Shaking head exaggeratedly for no apparent other reason	79	0.11	91	92	88	79	160	0.16	0.07	0.13	0.19	0.01
In H2O	Playing, splashing in water	60	0.08	60	64	86	93	486	0.03	0.15	0.05	0.16	0.02
Paw	Pouncing around and pawing at things; appears pleasurable	49	0.06	49	109	51	80	110	0.07	0.04	0.10	0.10	0.01
Paw/hit self	Pawing or hitting self	70	0.00	0	0	0	70	0	0.00	0.00	0.00	0.01	0.00
Tug	Tugging at an object while in self play	54	0.04	54	62	74	62	60	0.03	0.07	0.04	0.04	0.03
Bite air	Biting at air in erratic movements	395	0.00	0	395	0	0	0	0.00	0.01	0.00	0.00	0.00
Bite self	Biting at self in erratic movements	71	0.00	0	0	71	0	0	0.00	0.00	0.01	0.00	0.00
Bite object	Biting at an object in erratic, playful movements	59	0.02	59	59	67	77	0	0.07	0.01	0.01	0.02	0.00
Tear obj	Tear and chewing objects exaggeratedly	91	0.01	91	156	302	158	202	0.01	0.01	0.01	0.01	0.01
Push obj	Pushing objects with wide-eyes, exaggerated movements	221	0.00	0	221	0	391	382	0.00	0.01	0.00	0.01	0.01
Toss obj	Tossing an object (e.g., dead mouse) in air – usually repeatedly done	71	0.19	120	92	96	111	71	0.20	0.27	0.22	0.15	0.13
Head toss	Tossing objects such as food	39	0.00	0	39	171	0	0	0.00	0.01	0.01	0.00	0.00
Pounce obj	Pouncing on non-prey (usually just the ground); appears to be practicing hunting	51	0.03	98	73	51	158	97	0.03	0.05	0.06	0.01	0.02
Run ar	Erratically running around in circles	49	0.02	60	92	49	93	82	0.03	0.01	0.04	0.02	0.01
Roll	Rolling around while exaggerating movements	74	0.03	0	121	74	80	0	0.00	0.01	0.08	0.05	0.00
Jump	Jumping up and down	85	0.01	96	0	85	299	0	0.01	0.00	0.01	0.01	0.00
A/w	Bouncing back and forth almost like it can't decide where to go	53	0.01	192	0	53	93	225	0.01	0.00	0.04	0.01	0.01
N = 20	Total percentage for self-play (PS):		1.50						1.43	1.33	2.32	1.68	0.75
Play Initiation (PI)	Play initiation; actively soliciting play with others; previously not engaged in play before doing PI with a Coyote	27	0.08	33	40	38	27	35	0.12	0.06	0.06	0.08	0.07
Gm	Same as play general movements but trying to initiate play with other(s)	27	0.01	52	0	154	27	0	0.01	0.00	0.01	0.03	0.00
Wag tail	Wagging tail and showing play face to another Coyote(s)	148	0.00	0	161	0	221	148	0.00	0.01	0.00	0.01	0.01
Bow	Front legs low and hind legs up; tail wagging common	39	0.05	39	47	93	39	39	0.07	0.05	0.03	0.07	0.04
Bark	Barking at others often followed by a play bow	78	0.00	0	0	78	0	0	0.00	0.00	0.02	0.00	0.00
SuP	Exaggerated, friendly position with paws in air trying to get another near it	363	0.00	0	0	0	0	363	0.00	0.00	0.00	0.00	0.01
Approach	Approaching another Coyote with play face, usually walking	47	0.01	0	47	0	73	79	0.00	0.01	0.00	0.01	0.01
A/W	Rapidly approaching and withdrawing from a Coyote trying to initiate play with that Coyote	44	0.07	52	47	51	62	44	0.06	0.06	0.10	0.07	0.08
A/w gr	Same as above but in a group	128	0.00	128	0	0	0	0	0.01	0.00	0.00	0.00	0.00
SuA-ea	An exaggerated active submission posture trying to get another to play	45	0.00	0	0	0	0	45	0.00	0.00	0.00	0.00	0.01
Bump other	Deliberately bumping into another to initiate play	85	0.01	0	85	0	106	107	0.00	0.02	0.00	0.01	0.01
Paw	Pawing at another Coyote trying to get it to play	62	0.03	85	62	113	82	97	0.02	0.03	0.03	0.06	0.03
Face paw	Pawing at another in the face	27	0.01	0	0	0	27	0	0.00	0.00	0.00	0.03	0.00
Flaunt with obj	Trotting around with object in mouth trying to get other(s) involved	126	0.00	0	0	141	126	0	0.00	0.00	0.01	0.01	0.00
Bite	Biting another in a playful manner	51	0.04	59	131	51	67	99	0.05	0.04	0.06	0.01	0.03
Bite at/intentions	Biting at another in a playful manner but making no contact	51	0.06	137	153	51	80	68	0.03	0.01	0.08	0.10	0.08
Jump	Jumping in the air near another Coyote	73	0.01	73	124	167	0	0	0.01	0.01	0.01	0.00	0.00
LL	Same as Play LL but trying to solicit play	48	0.01	0	48	59	0	0	0.00	0.01	0.02	0.00	0.00

TABLE 1. Ethogram on eastern Coyotes *(continued)*

Parent Subcategory	Description	Age	%	Age					%				
		All 5	All 5	Cane	Caon	Late	Lupe	Trans	Cane	Caon	Late	Lupe	Trans
Pounce	Jumping in front of another Coyote	59	0.02	64	77	59	0	0	0.04	0.02	0.04	0.00	0.00
Run around	Running quickly around trying to get others to join the chase	39	0.03	60	79	85	148	39	0.03	0.01	0.01	0.03	0.06
Run w object	Same as above but with something in its mouth	150	0.00	177	0	150	0	0	0.01	0.00	0.01	0.00	0.00
Bite and run	Nipping another playfully then running around	199	0.00	0	0	0	199	0	0.00	0.00	0.00	0.01	0.00
Ch	Chasing a Coyote to try and start a game of chase	47	0.00	0	47	0	0	81	0.00	0.01	0.00	0.00	0.01
Circling	Circling another with play face apparent	75	0.00	0	75	0	102	0	0.00	0.01	0.00	0.01	0.00
N = 24	Total percentage for PI:		0.46						0.46	0.35	0.48	0.54	0.47
Play (P)	Social play; see text for the characteristics of play; exaggerated and unpredictable movements; pleasurable activities; play face apparent	33	1.73	33	34	38	34	33	2.26	1.85	1.14	1.47	1.91
Group (gr)	General group (≥2 Coyotes) play where a lot is happening but one thing doesn't predominate like wrestling or playing	42	0.36	47	42	51	60	47	0.33	0.32	0.47	0.35	0.34
Periphery	Mocking the movements (running, wrestling) of the 2 Coyotes playing; done at the edge (1-2 m away) of the Coyotes	47	0.01	0	0	47	0	0	0.00	0.00	0.07	0.00	0.00
Periphery gr	Same as above but ≥3 of the Coyotes are playing	52	0.01	0	0	52	0	0	0.00	0.00	0.07	0.00	0.00
Gm	General movements such as walking around others, moving head and eyes; erratic movements; basically, play was occurring but it was hard to classify in any other category	33	0.07	33	98	185	52	33	0.07	0.05	0.03	0.12	0.07
Gm gr	Same as above in a group	102	0.19	162	167	162	102	103	0.20	0.14	0.13	0.32	0.18
Eee	Making a squealing sound during play	65	0.00	65	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Growl	Play growling without serious threats	81	0.00	0	0	81	0	0	0.00	0.00	0.01	0.00	0.00
Paw other	Pawing another Coyote during play	33	0.01	45	0	85	0	33	0.02	0.00	0.01	0.00	0.01
Face paw	Pawing another Coyote in the face during play	49	0.01	49	0	0	52	0	0.01	0.00	0.00	0.03	0.00
Head shake other	Grabbing neck with mouth and head shaking another during play	155	0.00	0	0	0	155	0	0.00	0.00	0.00	0.01	0.00
Bow	Lowering foreleg and elevating hind leg while wagging tail in the middle of play	43	0.01	0	0	0	43	43	0.00	0.00	0.00	0.02	0.01
LL	Leap-leap; two successive leaps during play	27	0.01	0	34	0	27	48	0.00	0.02	0.00	0.03	0.01
Walk around	Play face apparent while Coyotes are walking; play is occurring before and after these short walks; for example, this usually occurs in between wrestling bouts	125	0.01	0	0	125	0	0	0.00	0.00	0.03	0.00	0.00
Wk as gr	Same as above but while in a group	126	0.00	0	0	0	126	0	0.00	0.00	0.00	0.01	0.00
Trot around	Same as above but while trotting	80	0.03	80	284	0	174	330	0.03	0.01	0.00	0.08	0.02
Trot with coy	Trotting with Coyote with play-like body gestures	142	0.00	142	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Trot gr	Same as above but while in a group (≥2 others)	163	0.02	257	0	323	163	297	0.07	0.00	0.01	0.03	0.02
Run around	Same as above but while running	39	0.08	60	73	49	44	39	0.14	0.02	0.06	0.04	0.14
Follow/trot	Same as above but while following another Coyote; again, clearly play is occurring during these activities	54	0.05	71	92	60	54	68	0.04	0.06	0.04	0.03	0.11
A/W	During play, another Coyote approaches and withdraws from another Coyote	44	0.07	44	86	53	97	48	0.06	0.07	0.10	0.05	0.04

A/W gr	Same as above but in a group (≥2 others)	98	0.04	98	141	141	120	99	0.03	0.04	0.03	0.05	0.08
Ch	One Coyote full speed chases another Coyote around	39	0.86	39	39	51	39	39	0.95	0.62	0.61	0.79	1.34
Ch gr	Same as above but in a group (≥2 others)	55	0.53	80	80	81	58	55	0.63	0.33	0.36	0.54	0.77
Periphery ch gr	Same as above but in a full speed chase; this Coyote has no contact with the group during play bout	167	0.00	0	0	167	0	0	0.00	0.00	0.01	0.00	0.00
Circle	Two Coyotes circle each other; other play actions occur before and/or after these encounters	45	0.05	45	153	144	148	47	0.02	0.06	0.04	0.02	0.08
Circle gr	Same as above but with ≥2 other Coyotes	115	0.12	154	170	162	115	129	0.10	0.08	0.12	0.13	0.18
Hide-n-seek	One Coyote hiding and another finding it; chasing usually occurs after this	52	0.04	52	55	59	72	52	0.03	0.05	0.03	0.03	0.06
Tug o war	At least 2 Coyotes pulling simultaneously on an object (branch)	48	0.22	54	48	51	51	48	0.23	0.27	0.11	0.36	0.14
Tug o war gr	Same as above but with ≥2 other Coyotes	111	0.07	111	124	125	111	0	0.17	0.01	0.03	0.11	0.00
Wrestle (Wr)	Two Coyotes wrestling each other; fighting not observed	27	1.36	38	39	34	27	39	1.61	0.79	0.94	1.36	2.11
Wr gr	Same as above but with ≥2 other Coyotes	45	0.42	45	48	85	79	55	0.54	0.25	0.20	0.46	0.65
Wr wk	Walking while wrestling	543	0.00	0	0	0	543	0	0.00	0.00	0.00	0.01	0.00
Wr trot	Trotting while wrestling	60	0.00	0	0	60	405	0	0.00	0.00	0.01	0.01	0.00
Wr Sup	During play one Coyote submits to another and will wrestle from a SuP position; role reversal often occurs where a more dominant Coyote submits	44	0.19	44	71	51	73	44	0.27	0.06	0.15	0.12	0.35
Wr SuP gr	Same as above but with ≥2 other Coyotes	55	0.06	80	71	105	99	55	0.03	0.07	0.10	0.05	0.04
Pinning	Opposite of SuP where 1 Coyote pins another; role reversal is common here where the less dominant Coyote is the pinner	37	0.20	40	40	78	37	65	0.21	0.19	0.19	0.20	0.22

Roll	Rolling on the ground	102	0.02	102	0	298	0	0	0.03	0.00	0.05	0.00	0.00
Jump	Jumping to something like on a rock or box; occurred in different contexts than other jumps (e.g., during self play or play initiation)	39	0.05	39	47	49	58	52	0.13	0.07	0.02	0.01	0.04
Climb	Climbing on objects (e.g., fence)	33	0.01	35	40	43	0	33	0.03	0.02	0.01	0.00	0.01
Crawl	Belly on the ground; arms used to drag self around; hind legs propel self	59	0.00	59	0	0	0	0	0.01	0.00	0.00	0.00	0.00
Inguinal	Raising one hind leg to expose abdominal area when facing opposite direction of conspecific; difficult to classify; didn't seem to be greeting or agonistic towards one another	33	0.02	278	0	34	37	33	0.01	0.00	0.07	0.02	0.01
N = 9	Total percentage for MISC:		0.28						0.40	0.27	0.31	0.26	0.16

active in JGW's presence than other times of the day (Stone Zoo Keepers, personal communication).

Traveling T was defined as a Coyote moving with purpose from one place to another (i.e., from point A to point B). A Coyote, when traveling, would move in a straight line and would waste little energy investigating other objects until it reached its destination. This differed from explore/investigate E/I activities, where animals were characterized by actively sniffing objects or other Coyotes, digging, and moving around in a non-direct way in order to explore their surroundings. E/I behaviour is typically not described in the literature for canids (but see Scott and Fuller 1965) yet was an important activity that our Coyotes engaged in, by far the most frequently of any parent category (Table 1; 32% of activity). The difference between explore/investigate and traveling activities would be interesting to compare between wild and captive canids. The captive Coyotes that we studied were very active but did more exploring then traveling because of the relatively small area that they lived in. Conversely, Coyotes in the wild routinely have to traverse their home ranges (Camenzind 1978; Gese et al. 1996; Way 2000) and potentially might do more traveling than exploring.

Hunting (HU) behaviour was classified when a Coyote was actively trying to catch/kill another object. Many small mammals and birds entered their enclosure, giving the Coyotes the opportunity to hunt (although we occasionally gave them live chicken chicks, we never scored the Coyotes when they were killing them). Additionally, when a Coyote was attempting to ambush a conspecific, we also classified this as hunting because its intentions were very similar to hunting prey: i.e., body very alert and focused, in a crouched position, and rushing at its intended target. Furthermore, different results occurred after an ambush; e.g., no social interactions occurred (i.e., both individuals walked away from one another), a play initiation was given once the ambusher got within close range of the Coyote, play immediately started, or fighting or agonistic behaviour ensued. Parks (1979) classified "ambushing" as a separate category in her thesis but perhaps the larger size of the exhibit in which we studied our Coyotes allowed us to detect the similarity to hunting.

Feeding was simply associated with ingesting something. Although we documented our Coyotes feeding (FE) we attempted to avoid conducting behaviours around any type of feeding time (e.g., we did not do a behavioural bout when dog chow was just placed out or when meat, rats or mice were just given to them) to avoid biasing the data.

Infantile (IN) behaviours were associated with neonatal contact as described by Parks (1979), but we also included licking/grooming one another. Because the Coyotes were in contact with other Coyotes, we believed that this was an important division for a parent category even though other behavioural complexes, such as resting, sit1 and sit 2, are included in this category. These behaviours were intermittently seen

throughout the 18 months of observation when Coyotes would occasionally sleep on one another (especially on rainy days) or one Coyote would lick another but was not greeting it. A licking Coyote appeared to be grooming the recipient, which made it hard to place into any other category (i.e., it was doing more than simply greeting another Coyote).

Greetings (GR) were classified when non-agonistic and/or non-play interactions occurred between ≥2 Coyotes. Zimen (1982) classified many of these behaviours as neutral social contacts but we separated Zimen's descriptions of sniffing other Coyotes and left them in the explore/investigate category because the motivation was not always clear (e.g., was sniffing another Coyote a social contact or just a Coyote curious to smell another one?). Simply put, when both Coyotes licked and/or had muzzle contact with each other and/or wagged their tails in excitement to see one another, then we classified this as a greeting.

We used Bekoff's (1972a,b) definition of "play" to define our category, where play was the behaviour that was performed during social interactions in which there was a decrease in social distance between the interactants, and no evidence of social investigation or of agonistic or passive-submissive behaviours on the part of the members playing, although these actions may occur as derived acts during play (e.g., passive submission during a play bout). Bekoff (1974) also classified play as: (1) incorporating various contexts into unpredictable temporal sequences; (2) preceded by a metacommunicative signal (which we have a separate category for: i.e., play intitiation); (3) certain actions are repeated and performed in an exaggerated manner; and (4) the activity appears pleasurable to the participants: a play face (wide open jaws and eyes) is apparent.

We also included the numerous role reversals in this category where more dominant Coyotes allowed lower ranked Coyotes to pin them to the ground; this was never documented during agonistic displays. Bekoff (1974) includes a description of this occurring amongst western Coyotes but does not delineate it as part of classifying play. Additionally, we separated play initiation from play because the attempter was not always successful in initiating play during an attempt; i.e., they appeared to be two separate categories. We observed many play initiation-like (e.g., approach/withdraw and general movements) behaviours occurring during play, but because they happened during play we kept them in this category; i.e., play was already initiated. Self play (PS) was similar to play but when a Coyote was by itself. Altogether, play-like sequences accounted for ca. 10% of all observations (Table 1).

Agonistic (AG) behaviours were classified as aggressive acts associated with conflict where there were clear acts of dominance and submission or where growling or fighting was observed (Fox 1969; Scott and Fuller 1965; Zimen 1982). About 2% of all activities were aggressive, especially towards the end of the study when Coyotes were separated. Finally, a miscellaneous (MISC) category was one where we could not classify the behaviour pattern into any of the other parent systems; these were very infrequent (Table 1).

Despite the large number of behavioural patterns described herein, there are some important omissions in our ethogram. First, because the Coyotes were all siblings and were young adults (18 months) when the study ended, we did not notice any sexual/reproductive behaviours (although it was witnessed during their second winter: J. Way, unpublished data). Future ethograms should add this behaviour as a separate (parent) category much as Scott and Fuller (1965), Zimen (1982), and Goodmann and Klinghammer (1990) did with their respective ethograms. Second, because the Coyotes were taken from the wild at 25 days of age, we missed many basic neonatal behaviours, such as crawling and nursing (Scott and Fuller 1965; Scott 1967; Parks 1979). Third, because the Coyotes were all siblings and of the same age, we could not document any adult-pup interactions such as epimeletic behaviours, i.e., the giving of care (Scott and Fuller 1965). However, many times we did document et-epimeletic behaviours where the Coyotes were soliciting or calling for care where they would whine, wag their tails for a greeting (with JGW and/or another Coyote), and lick one another. Fourth, the full range of hunting behaviours (e.g., killing/biting prey) was not documented mainly because of the rarity of observing a kill – especially during the 15 sec intervals when we recorded data. Finally, there were some different behavioural actions that we could have added but simply did not because of the sheer volume of our ethogram. For example, under infantile behaviour we have sit1 and sit2 although we do not note if their eyes are open or closed. Because both examples were rarely observed, this was a minor detail in the overall scheme of Table 1, but it does illustrate the arbitrarily defined nature of any ethogram (Schleidt et al. 1984), no matter how simple (i.e., the parent categories) or complex (i.e., the behavioural actions) it is. Also, we thought that sit1 and sit2 were logical separations due to the noticeably different body positions; however, we theoretically could have had many more sitting positions based on a combination of head, body, and leg positions.

Although we attempted to be consistent with our behavioural classifications, there was no doubt that drift occurred in our categorizations (MacDonald et al. 2001). For example, many of the behaviours occurred well before first noted on Table 1. Although usually very similar to other categories (for example E/I wk sn and E/I st sn versus E/I step sn; Table 1) a new category randomly created during the study certainly introduces a bias to the finally tally of percentages in Table 1. However, the goal of this study was to produce an end product (i.e., the ethogram) even at the expense of being consistent throughout – i.e., there was no available model of a typical ethogram on wild canids. Also, a number of simple, but newly recorded, behaviours occurred after the study concluded. For example, E/I step sniff became much more frequent no doubt because of the new category described not because a Coyote just started doing that action pattern. Also, stand step alert and stand alert move head were described soon after this ethogram was finalized (J. Way, unpublished data). Although these were commonly recorded after the Coyotes were separated they

were not described herein. That being said, we believe that the ethogram is largely complete and that these slight nuances are offset by our rationale of producing the ethogram when all five Coyotes were housed together (i.e., before they were permanently separated) and the fact that the main categories would stay virtually identical even with these changes.

The categories that we created are intended for ease of use in the field where a researcher can simply note the major behavioural system observed and the behavioural pattern associated with it. One advantage of this ethogram is that it is in discrete units (i.e., the behavioural patterns). However, data could always be lumped together (i.e., into general behavioural systems or ≥2 behavioural patterns could potentially be combined into one action) if the data/list are unmanageably large (e.g., when studying wild Coyotes). The disadvantage of merging behaviours into more broad groupings is that parent categories or lumped behavioural patterns can never be split back into more distinct behavioural patterns if not done at the outset; as Bekoff (1972b) indicated, this would cause data to be irreversibly lost.

The previous studies that have described canid behaviours were quite variable (Scott and Fuller 1965; Silver and Silver 1969; Bekoff 1972a; Parks 1979; Zimen 1982) so we basically combined data/categories from all of these studies and made modifications or additions as needed in order to try to create an accurate yet practical guide for researchers studying canids in the field. Future research should try to generate similar ethograms for other species and should continue to modify and/or expand our list if new behavioural actions are found with Coyotes. Analyzing ethograms of closely related species may be one technique to effectively discriminate between them (e.g., Western Coyotes, Eastern Coyotes and Wolves – Silver and Silver 1969; Bekoff 1978).

Acknowledgments

This study would not have been possible without the support from the staff at Zoo New England, including the keepers, management, veterinarians and their technicians, and security. In-kind benefits from the Way family were invaluable. Peter Auger and the Biology Department and Urban Ecology Institute at Boston College provided support. Katie-Jo Glover and Kelly Holland assisted with data entry. The Town of Falmouth's Animal Control and Department of Natural Resources were instrumental in helping JGW obtain the wild-born pups.

Richards, Ngaio L., Pierre Mineau, David M. Bird, Pierre Wery, Jacques Larivée, and Jason Duffe. 2006. First observations of an Eastern Screech-Owl, *Megascops asio*, population in an apple-producing region of southern Quebec. Canadian Field-Naturalist 120(3): 289–297.

Baseline information was collected on a local Eastern Screech-Owl population found in the apple-producing region of Saint-Hilaire and Rougemont, Quebec, as part of a larger study on pesticide exposure conducted between 2000 and 2003. Screech-Owls visited or occupied 41 of 89 nest boxes installed in 12 orchards and 2 control locations. The mean height of occupied nest boxes was 3.83 m (2.00 – 5.80 m). Squirrels, *Sciurus* and *Tamiasciurius* sp., and chipmunks, *Tamias striatus*, Northern Flickers, *Colaptes auratus*, and wasps were the owls' primary competitors for the boxes. Intact Screech-Owl pellets retrieved from nest boxes (n = 82) had a mean length and width of 3.57 and 1.44 cm, respectively, and weighed a mean of 1.77 g. Screech-Owls in the study area consumed a variety of small mammal, avian, insect and aquatic prey. Of these, Meadow Voles, *Microtus pennsylvanicus*, were the predominant prey item identified in pellets, and Mourning Doves, *Zenaida macroura*, were the primary avian prey found in nest boxes. In Canada, the owl's trend status remains largely unknown. The species is currently listed as "Not at Risk", based on an assessment conducted for COSEWIC in 1986. Given that a limited amount of information exists on the natural history and ecology of the species in Quebec, we also generated a map of the owl's distribution in the province, using data from ornithological databases and rehabilitation facilities. Potential risks to the species within the province, particularly pesticide exposure and habitat loss, are briefly addressed and follow-up studies are discussed.

Key Words: Eastern Screech-Owl, *Megascops asio*, natural history, ecology, apple orchard, Quebec, range, distribution, census, pellet analysis, prey inventory, nest box, wing chord, population management, pesticide exposure, habitat loss, development, conservation.

The Eastern Screech-Owl, *Megascops asio*, has been extensively studied in the United States (i.e., VanCamp and Henny 1975; Gehlbach 1994a). However, it has received considerably less attention north of the border, where it occupies a much smaller area. Within Quebec, the Screech-Owl's range is vaguely delineated and general knowledge about the species is limited. As part of a study assessing the exposure of the Screech-Owl to pesticides currently and previously used in apple orchards of southern Quebec (see Richards et al. 2004, 2005), we collected baseline information on the species. Here, we present observations on a population of Eastern Screech-Owls (Figures 1, 2, 3 that resides in one of the primary apple-producing regions of Quebec.

Methods

Mapping the range of the Eastern Screech-Owl in Quebec

We obtained case files from the Clinique des oiseaux de proie (COP), based in Saint-Hyacinthe, and the Center for the Rehabilitation of Injured Birds of the Montérégie (CRIB), based in Otterburn Park, which administer care to the majority of injured or orphaned owls in the province. The locations from which adult and juvenile Screech-Owls were admitted were tabulated and mapped. These data harbour certain biases and so were used only to illustrate the overall, rather than density, distribution of the species within Quebec. For example, the number of owls admitted from an area is positively correlated with its proximity to the nearest rehabilitation facility (Richards et al., unpublished data). Visibility and predisposition to capture can artificially inflate admission numbers; in this case facilities tend to receive an influx of orphaned Screech-Owl babies and fledglings in the late spring and summer, largely from suburban settings, where they are highly conspicuous (Richards et al., unpublished data). Thus, each admission location was given one data point, and multiple admissions from any given area were not considered an indication of a large Screech-Owl population or that it was especially suitable for the species.

We also obtained Screech-Owl locations from the Études des populations d'oiseaux du Québec (ÉPOQ) database, which is managed and continually updated by members of ornithological clubs and societies belonging to the Association québécoise des groupes d'ornithologues (AGQO). Finally, we contacted personnel from the Ontario Breeding Bird Atlas project (OBBA) and from the New Brunswick division of Bird Studies Canada to ensure that our map represented the species' range at the eastern and western borders of Quebec as precisely as possible.

Site selection and censusing

All fieldwork was carried out in orchards of Rougemont and Saint-Hilaire (45°28"73°W to 45°32"73°N), two adjacent apple-producing regions of southern Quebec. The study region was first surveyed in the summer of 2000 for areas containing habitat requirements for Screech-Owls; i.e., mature and mixed forest with old cavity-ridden trees and conifers for shelter, as well as running water. Potential orchards and control sites were then censused between November and March 2000 and 2002. By November, most first-year individuals should have dispersed from their natal habitat and established a territory. Thus, owls that respond are likely to be established, rather than transient, individuals. This provides a "true sense" of occupancy. We have found, based on our experience censusing Screech-Owls in southern Quebec, that this timeframe also corresponds to the period when individuals are reasonably responsive to broadcast calls.

We walked or snowshoed between the edge of the orchard and the adjacent forest, broadcasting a combination of "bounce" (territorial) and "whinny" (defensive) calls into the forest from a small, hand-held tape player. Between 3 and 7 minutes of silence followed, and then the calls were repeated. If a response was not obtained, we then proceeded around the perimeter and repeated the process roughly 10 minutes later. When a response was obtained, the presence of an individual was visually confirmed with a headlamp or flashlight and its colour phase was noted. Two individuals observed in the immediate vicinity of one another (i.e., perched in the same tree) were considered a pair. We also noted responses from Barred Owls, *Strix varia*, or Great Horned Owls, *Bubo virginianus*. The presence of these potential predators in an area may cause Screech-Owls to suppress vocalizations (Fuller and Mosher 1981), restrict the size of their territory, or deter them from establishing themselves altogether (Gehlbach 1994a).

The locations were then re-censused every winter to verify whether or not they were still occupied. The 12 orchard and 2 control sites where Screech-Owls were observed in the winter were censused again in June and July of 2001 and 2002. Given that Screech-Owls are not always particularly cooperative even under optimal conditions, locations were repeatedly censused (at least twice) if a response was not obtained during the first censusing effort. We did not census when wind speed exceeded 15 km/h, or during rain or snow, to ensure that censusing was carried out under the best possible conditions.

Nest box installation and inspection

Between 2000 and 2002, 89 nest boxes were installed in the forests where Screech-Owls responded during our initial censusing efforts. All orchards were assigned a letter code to maintain orchard-owner confidentiality. Boxes were constructed of pine, *Pinus* sp., or Eastern Hemlock, *Tsuga canadensis*, with dimensions for American Kestrel, *Falco sparverius*, as per Henderson (1992). Material does not appear to influence nest box selection by Screech-Owls (Gehlbach 1994b). One caveat is that boxes made of hemlock must be stored under conditions of relatively uniform heat or they will crack and warp. Pine boxes are heavier and more challenging to transport but much more resistant to temperature fluctuations, both inside during storage and in the field.

Between 1.0 and 2.0 inches of dust-free wood chips were placed in the bottom of each box. The distances from the base of the box to the ground and from the box to the nearest orchard edge were recorded. Nest box covers were secured on each side with spring-loaded latches to facilitate inspections while minimizing entry by mammalian predators, particularly Raccoons, *Procyon lotor*. Though most locations were fairly remote, boxes installed in areas regularly accessed by the public were painted with a brown, non-toxic paint, and placed a greater distance from the ground to reduce visibility and the possibility of disturbance or vandalism (as described in Gehlbach 1994b).

Boxes were initially inspected for pellets and prey remains 3 to 4 times per year: in the spring, in mid to late summer, in the late autumn and in the early winter, depending on ease of accessibility to each site especially during periods of heavy snowfall. However, we soon stopped inspecting in the spring and summer because of the disturbance posed to other species occupying the boxes; unfortunately, we unwittingly caused nuthatch, *Sitta* sp., and European Starling, *Sturnus vulgaris*, parents to abandon their nests. From an ethical and logistical perspective, the late autumn and early winter were deemed the best times to inspect nest boxes. Thus, between 2003 and 2004, boxes were inspected once or twice per year in the late autumn and/or early winter. When prey items were found, boxes were emptied and replenished with wood chips to prevent duplication of results on subsequent visits. Recovered wood chips were carefully sifted for pellets or prey items.

Pellets, prey remains and prey inventory

Pellets were air-dried prior to dissection for prey identification. Length, width and weight of intact pellets were recorded. Small mammal species were identified by lower mandible (Cahn and Kemp 1930; Rac-

zynski and Ruprecht 1974), using a reference collection of known skulls and mandibles. Vole species were further distinguished as *Clethrionomys* or *Microtus* sp. using Maisonneuve et al. (1997). Avian prey were identified to species from feather remains with the help of two local wildlife rehabilitators, and referring to Elbroch and Marks (2001). An inventory was then drawn up for each of the locations where prey items were found.

Screech-Owl captures

Screech-Owls were initially captured between June and August of 2001 and 2002 as part of an unsuccessful attempt to radio-track them and evaluate their use of orchards in relation to pesticide applications. We set up a mist net and a bal-chatri trap baited with a white mouse within orchards but near adjacent forest (as per permits no. 2001-05-07-103-16-SF and 2002-06-10-120-16-SF). We then broadcast defensive and territorial calls into the forest to attract owls. Capture attempts were initiated just prior to or soon after dusk.

All captured adults and young were processed on-site. First, they were placed headfirst into a clean Pringles® chips canister and weighed with a 300 g spring-loaded Pesola scale. After the owl was removed from the canister, the keel region was gently palpated and a keel index was assigned on a scale of 0 to 5, with 1 being "emaciated", 3 being of "medium" weight, and 5 being "obese". The wing chord was also measured. Owls were aged as adults based on the presence of blood feathers and on other evidence of moulting. It was not possible to sex individuals. All owls were banded and released.

Results

Range map

One hundred and sixty-nine locations were plotted: 20 from the COP (records spanning 1998 to 2001), 17 from the CRIB (records spanning 1988 to 2003), 7 from the OBBA (2001 to 2004 data) and 125 from the EPOQ database (1940 to 2004). According to the personnel at the New Brunswick division of Bird Studies Canada, the species is incidental at best in the Maritime provinces, and they were unable to provide us with definitive sightings.

Censusing

Between the winters of 2000 and 2002, we censused 27 orchards and 3 potential control sites. We received a response from Screech-Owls in 12 orchards and 2 control sites, one a wooded area near a trailer campground and the other in the research sector of the Mont-Saint-Hilaire Biosphere Reserve. Four pairs and 7 individuals were observed during censusing and all were grey-phased.

Great Horned Owls or Barred Owls were heard or seen in the vicinity of 6 of the 14 locations occupied by Screech-Owls and 6 of the 16 remaining locations. It is likely that some or all of the locations where we did not obtain a response are frequented by one or both species; the habitat observed is suitable and they are all either quite close to the Mont-Saint-Hilaire Biosphere Reserve or to Mont Rougemont, both of which have Great Horned Owl and Barred Owl populations (C. Cormier, personal communication 2003).

FIGURE 1. Distribution of the Eastern Screech-Owl (*Megascops asio*) in Quebec.

Nest box occupation

A nest box was considered occupied if pellets, prey remains or an owl were observed in it during inspections (Table 1). To determine whether height of nest box or distance from box to nearest habitat/forest edge influenced its selection or use, we first considered the height and distance of those boxes occupied *at least once* by a Screech-Owl. Then, we further refined our analysis to nest boxes for which we had evidence of multiple uses, defined as three visits or more (Table 2): either evidence of occupancy on at least three separate nest box inspections or discovery of at least three pellets or prey remains, given that Screech-Owls generally regurgitate one pellet per resting period.

We measured the distance from the tree on which nest boxes were installed to the nearest "true' edge", an important distinction as a network of paths criss-crossed most of the forests in which boxes were installed. True edge was defined as an expanse of open area immediately adjacent to, rather than contained within, the forest itself, such as a field or an orchard. Box distance ranged from 0 to 68.0 m from edge.

TABLE 1. General nest box occupancy of Eastern Screech-Owls, by location, in Saint-Hilaire and Rougemont, Quebec areas (2000 – 2004).

Location	Number of boxes installed	Percent occupation
Campground	9	89
Biosphere Reserve	6	100
A/A1	7	14
B	10	30
K	8	25
C	5	20
D/F	10	100
G	7	14
I	11	0
M	7	29
N/N1	9	78
Total	89	

A variety of other species occupied the nest boxes (see Table 3). To determine the overall frequency of nest box use, we evaluated the total number of times boxes were occupied by Screech-Owls at each site over the course of the study relative to other species. Table 4 shows occupation by the most commonly observed species in relation to that by Screech-Owls.

Pellets and prey remains

Nest boxes were installed at the 12 orchards and 2 control locations where Screech-Owls responded to censusing. However, in some of these locations, there was little or no evidence (i.e., pellets or prey remains) that Screech-Owls ever occupied these boxes. Only one pellet was found at Orchards A/A1, C and M, so these were excluded from the prey inventory analysis (Table 5). Intact pellets were retrieved from 8 of the orchards, including C and M, which *were* included in the analysis of pellet dimensions.

TABLE 2. Mean height from ground of nest boxes ($n = 41$) occupied by Eastern Screech-Owls in Saint-Hilaire and Rougemont areas, Quebec (2000 – 2004).

	Height from ground (m)	Range
Unoccupied boxes ($n = 48$)	4.22	2.40 – 6.82
Occupied boxes ($n = 41$)	3.83	2.00 – 5.80
"High-use" nest boxes ($n = 33$)	3.67	2.00 – 4.72

Screech-Owl captures

Despite repeated censusing, a response was never obtained in Orchards G or M. These locations were therefore excluded from capture attempts. We did obtain a response in Orchard C, but the owl never deigned to approach our traps.

Nine individuals were captured in the summers of 2001 and 2002. On occasion, Screech-Owls began to respond to broadcast calls while some daylight remained. However, owls were always captured under cover of darkness, between 21:15 to 03:10. Though we were not always able to capture all the individuals observed, we did record their presence (see Table 6). Of the nine captured individuals and six observed, but not captured, only one was red-phased; the rest were grey.

Discussion

Eastern Screech-Owl range in Quebec

The Eastern Screech-Owl's northernmost North American range coincides with the southern tip of Quebec (Gauthier and Aubry 1996). To the west of Quebec, the species is commonly reported along the southern edge of Ontario in the Carolinian zone along Lake Erie and Ontario. More local and uncommon populations extend up another 100 to 200 kilometres north. In eastern Ontario, there appears to have been

TABLE 3. Nest box occupancy by other species.

an overall expansion of the range in the last 20 years (M. Gahbauer, personal communication, 2004). To the east of Quebec, the range may extend into the extreme southwestern part of New Brunswick (Gauthier and Aubry 1996); however, there are no confirmed breeding records for the species there. If Screech-Owls do in fact breed in New Brunswick, it is likely to be in very low numbers (B. Whittam, personal communication, 2004). Screech-Owls have also been observed in Nova Scotia and in Prince Edward Island, but their presence there is thought to be incidental (*ibid*). Elsewhere in Canada, the range is defined as extending from southwestern Saskatchewan to southern Manitoba (Panak 1988*). All of the above suggests that an important proportion of the species' range in Canada occurs in Quebec and in Ontario.

Censusing

For our purpose, which was to confirm the presence of resident Screech-Owls at a given location, we found the optimum census period to be between November and February. There are several logistical advantages to censusing towards the beginning of this period. During the early winter months, pairs jointly defend their territory and are very responsive to broadcast calls. As a result, there is a greater likelihood of obtaining a response from both the male and the female, which eliminates the need for speculation as to whether or not a location is occupied by a pair. Later on, heavy snowfall can lengthen the time required to census each location considerably, and render some virtually inaccessible.

Censusing can have adverse effects. In late February and early March, females select a suitable nesting location, then remain in or near their cavity. Broadcast calls may elicit a response from territorial males, but

FIGURE 2: A grey-phase Screech-Owl discovered during a mid-winter census at the Réserve écologique Marcel-Raymond, Henryville, Quebec, near the Richelieu River. Photographed by Léopold Gaudreau, Assistant Deputy Minister, Sustainable Development Branch, Ministère du Développement durable, de l'Environnement et des Parcs, 9 December 2006.

FIGURE 3. An Eastern Screech-Owl peers sleepily from a cavity at Parc Summit on the Island of Montreal. As development within the province increases, so too does the importance of the parks and protected areas within the species range. Photo by Jean-Sébastien Guénette, 17 April 2005.

given the necessity of devoting their energy to provisioning their mate and themselves, and to defending their territory against real rather than perceived intruders, censusing at this time can impose an unnecessary and potentially harmful stress. Predators of the Screech-Owl can also be attracted to the broadcast calls, and to respondents, especially if illuminated by a flashlight or headlamp. We are aware of one instance, for example, where a Long-eared Owl, *Asio otus*, was drawn to a Screech-Owl during censusing and was illuminated in the process of closing in on it. Since this study, a "minimal-disturbance" censusing protocol has been developed for the Screech-Owl and for other owl species (see Balej 2006).

Nest Box inspections

Nest boxes ($n = 89$) were installed in the vicinity of where Screech-Owls responded during censusing. Ordinarily, an owl's presence in an area would go largely undetected because they are very inconspicuous and occupy natural cavities. As the study progressed, our primary concern became to place the nest boxes at a height that would reduce the possibility of drawing untoward human attention to them. Overall nest box occupation at each location varied from 0% to 100%. Forty-one boxes were occupied at least once by an owl, and these boxes were a mean of 3.8 m (2.0 to 5.8 m) from the ground (Table 2). Gehlbach (1994b) found owls nesting, on average, 3.7 m from the ground in natural cavities ($n = 23$).

A number of species may compete with Screech-Owls for nest boxes. The four most frequent occupants were squirrels, *Sciurus* and *Tamiasciurius* sp., and chipmunks, *Tamias striatus*, Northern Flickers, *Colaptes auratus*, and Hymenoptera, especially wasps. During pre-snowfall inspections in October and November, we frequently removed nesting material left by other species, and during inspections the following spring found Screech-Owl pellets and prey remains. Occasionally, Screech-Owls deposed chipmunks and squirrels, judging from pellets or prey remnants deposited over nesting material. Northern Flickers have been reported to destroy Screech-Owl eggs (Penak 1986*). However, the Screech-Owls in our region infrequently (22 of the 146 recorded times) occupied nest boxes in the summer and early autumn months, when Flickers occupied them. Late autumn inspections enabled us to remove nesting material left by other species (or by Screech-Owls during the winter). We also could replenish the boxes with wood chips during these visits without having to disturb any of the species that had previously occupied the boxes and make any necessary repairs.

Pellets

The intact pellets retrieved from nest boxes ($n = 82$) ranged widely in length from 1.0 to 8.5 cm and from 0.8 to 3.2 cm in width, with a mean weight of 1.77 g. Elbroch and Marks (2001) recovered Screech-Owl pellets ($n = 18$) from nearby Vermont and New Hampshire which ranged from 1.6 to 3.8 cm length and 0.9 to 1.4 cm width. Fifty-six of our pellets exceeded the upper length and width reported by Elbroch and Marks. Most of the intact pellets we measured were retrieved from nest boxes, where they were protected from the elements and from breaking. This, and our larger sample size, may explain the discrepancy in our upper reported length.

Prey Consumption

Meadow voles were the predominant intact prey item found in our nest boxes. Screech-Owls are also highly insectivorous (Ritchison and Cavanagh 1992), and although we repeatedly found evidence of insect consumption, we were unable to fully assess or quantify it. Only insects with hard parts, such as beetles, *Coleoptera*, can be distinguished in pellets. For the most part, we found only a dust of legs and carapaces intermingled with the wood chips and with other artifacts. Mourning Doves were the avian prey most frequently found in nest boxes, but few avian prey remains were found. Screech-Owls may simply prefer to pluck feathers on a perch or in a deeper tree cavity rather than in a nest box which feathers could potentially fill quite quickly. Hence, our prey inventory underestimates avian and insect consumption. As well, several cached frogs and shrews, and a decapitated vole, were also found in nest boxes at the Campground control site. On a number of occasions, remnants of crayfish and fish scales were recovered from this site, as well as pieces of a greenish membrane, which may have been a remnant from the frogs. The greatest diversity in prey items seems to have been consumed at the Biosphere Reserve.

Conclusion

The Screech-Owl is found in suburban, rural and agricultural habitats. It is considered to be one of the most ubiquitous owls in North America (Gehlbach 1995). There is, however, very little information available about the species' natural history and ecology, or about its density and overall distribution in Canada, where its status was last evaluated for the Committee on the Status of Endangered Wildlife in Canada over 20 years ago (by Penak 1986*). Paradoxically, the species is currently designated as "Not at Risk", even though there are no current data on its population trend status (http://www.cws-scf.ec.gc.ca/mgbc/trends/index.cfm?lang=e&go=info.bird&speciesid=3730).

An important part of the species' range in Canada occurs in southern Quebec, where it coincides with an agricultural belt and with the province's major apple-producing region. Screech-Owls are known to favour orchard habitats (Gauthier and Aubry 1996) where pesticides are intensively applied. Our study evaluating the exposure of Screech-Owls to pesticides currently and previously used in one of the largest apple-producing regions of southern Quebec provided an opportunity to collect information on the species' regional diet, record physiological parameters, evaluate occupation response to nest boxes and gain a sense of the density and distribution of the local population. As far as we know this is the first time that these types of data have been collected on the Screech-Owls of the area.

More baseline information of this type must be gathered for future monitoring and population management efforts throughout the owl's Canadian range. Changes in development and land use patterns must also be examined. While we found that exposure to DDE and organophosphorus pesticides warranted further investigation (see Richards et al. 2004, 2005), we also observed a marked increase in clearing and development of forested lands and orchards over the course of the study. We believe that loss of habitat and overall decrease in habitat quality currently pose a far greater threat to the local population than exposure to pesticides.

Our colleagues at the Quebec environment ministry (Ministère du Développement durable, de l'Environnement et des Parcs) have been conducting autumn and winter censuses in ecological reserves within the known range of the species since 2005. This is part of an ongoing study initiated to evaluate the relative risks that pesticide exposure and habitat loss/deterioration pose to Screech-Owls in southern Quebec (if interested in collaborating on this study, please contact N. Richards).

Even if the North American Screech-Owl population may not be at risk as a whole, we are concerned that habitat loss and modification may be adversely affecting regional populations. At the very least, a re-examination of the Screech-Owl's distribution and population status throughout its Canadian range, especially in Quebec and Ontario, is long overdue. If this adaptable and opportunistic species is being adversely affected, how does this bode for the more vulnerable species which occupy the same habitats?

Acknowledgments

We are grateful to the orchard owners of the study area, without whose collaboration this study could not have taken place. We thank Terry Ryan and Jean Gougeon for building industrial quantities of nest boxes. Doctors Guy Fitzgerald and Claude Lacasse of the Clinique des oiseaux de proie and Annemarie Roth of the Centre for the Rehabilitation of Injured Birds of the Montérégie provided us with Screech-Owl admission records. Stéphane Deshaies and Annemarie Roth helped identify avian prey remains. Ambroise Lycke, Christine Bourque, Patrick MacFarlane, Anke Roth, Gavin McMorrow, Jessus Karst, Hugo Gee, Mar-

cel Gahbauer, Tina Newbury, Amy Stevenson, Marisha Futer, Jean-Sébastien Guénette, Joanna Coleman and Anneli Jokela all provided invaluable assistance and/or training in the field. We thank Nicole Kopysh at the Ontario Bird Banding Atlas project and Becky Whittam at the New Brunswick division of Bird Studies Canada for information related to the Screech-Owl's distribution in these provinces. Caroline Cormier of Nature-Action, Québec Inc. and Gina Rossini provided information on the whereabouts of birds of prey in Rougemont and Saint-Hilaire. We are pleased to acknowledge the collaboration and hard work of Rodolph Balej and Marcelle Ruest at the Ministère de Development durable de l'Environnement et des parcs. Funding for this study was provided to N. L. Richards by the Fonds Québécois de la recherche sur la nature et les technologies and by the Canadian Wildlife Service, Environment Canada. Additional funding was provided through a Natural Sciences and Engineering Research Council of Canada (NSERC) grant to P. Mineau. Initial stages of the project were funded by Environment Canada's Science Horizons for Youth programme, in collaboration with World Wildlife Fund Canada. In particular, we gratefully acknowledge the continued funding and support provided by Bird Protection Quebec (BPQ) (formerly the Province of Quebec Society for the Protection of Birds – PQSPB).

Woodley, Stephen J., Greg Johnson, Bill Freedman, and David A. Kirk. 2006 Effects of timber harvesting and plantation development on cavity-nesting birds in New Brunswick. Canadian Field-Naturalist 120(3): 298–306.

We studied the abundance of cavity-nesting birds in forestry-related habitats in a region of Acadian forest in New Brunswick. We examined five reference stands of natural forest, a chronosequence of conifer plantations up to 19 years old (the oldest in the study area), two selectively harvested stands, and a 30-year-old naturally regenerated clear-cut. The species richness and abundance of cavity-nesting birds were higher in reference forest (average 10.0 species per stand; 5.3 territories per 10 ha) than in plantations (2.3/stand; 1.0/10 ha), selectively harvested stands (7.0/stand; 3.8/10 ha), or the naturally regenerated clear-cut (5.0/stand; 2.5/10 ha). A cluster analysis segregated the "community" of cavity-nesting birds of natural forest from those of other treatments. Of the various harvested stands and plantations, five with a relatively large number of residual snags clustered similarly in the cluster analysis, while those with no or very few snags also clustered together. We used arrays of nest boxes (12 per stand) to examine whether the availability of cavities was limiting the use of habitats otherwise suitable for foraging by cavity-dependent species. Nest-box use for nesting and roosting was much higher in the seven plantations examined (average 4.0/10 ha for nesting and 2.9/10 ha for roosting) than in three reference stands (each 0.3/10 ha), suggesting that the plantations were deficient in this critical-habitat element. Our results suggest that certain mitigations, such as leaving residual snags and living cavity-trees, would help maintain populations of some cavity-dependent birds in clear-cuts and plantations. However, some cavity-dependent species might not be accommodated by these mitigations and are potentially at risk in intensively managed areas, unless landscape-scale management plans ensure the survival of sufficient areas of older mixed-wood forest.

Key Words: Acadian forest, cavity-nesting birds, conifer plantations, critical habitat, forestry, management recommendations, nest boxes, New Brunswick.

The effects of forestry on biodiversity range over a wide continuum, depending largely on the intensity of harvesting and subsequent management (Hunter 1990; Freedman et al. 1994; Angelstam and Milkusinski 1994; Freedman 1995; Hagan et al. 1997; Niemi et al. 1998; Imbeau et al. 2001; McRae et al. 2001; Kimmins 2003). For instance, clear-cutting followed by intensive management to develop an even-aged monocultural plantation has relatively extreme effects, while the effects associated with selective-harvesting and natural regeneration are much smaller. In boreal Europe, for example, natural pine (*Pinus sylvestris*) forest has been converted extensively into commercially preferred, short-rotation conifer plantations (Esseen et al. 1997), resulting in large declines of birds dependent on older natural forest (Virkkala 1991). Similar changes are occurring in temperate- and boreal-forest regions of Canada, where older mixed-species forest is being converted extensively into conifer plantations (Niemi et al. 1998; Imbeau et al. 2001; McRae et al. 2001).

Cavity-dependent birds in temperate and boreal forest are generally most abundant and species-rich in older, uneven-aged, mixed-species stands (Hunter 1990; Schreiber and Decalesta 1992; Newton 1994; Freedman et al. 1996; Hobson and Schieck 1999; Schieck and Hobson 2000). Intensive forestry practices generally decrease the richness and abundance of cavity-dependent birds by causing the following habitat changes to occur (Niemi et al. 1998; Hobson and Bayne 2000; Flemming and Freedman 1998; Imbeau et al. 2001; Kirk and Machtans 2004; McRae et al. 2001):

- the conversion of natural forest having complex biological and physical structure (i.e., multi-species stand composition and intricate spectra of age and size) into silvicultural plantations dominated by a monospecific cohort of similar-sized and -aged trees
- the reduction in quantity of cavity trees, dead snags, and coarse-woody debris by intensive management practices (in Canada and elsewhere snag felling may even be required under health and safety regulations; e.g., Naylor et al. 1999)
- the truncation of stand age-at-maturity by short-rotation management (typically 40-60 years), which precludes the regeneration of large cavity-trees and coarse-woody debris

Moreover, at the level of landscape, forestry typically decreases the average age and complexity of habitat "patches," while isolating remnants of older natural forest (Hunter 1990; Freedman et al. 1994; Hagan et al. 1997; McRae et al. 2001). Landscape-scale forest management must accommodate species with extensive and specialized habitat needs, including some cavity-nesting birds dependent on older forest (Renken and Wiggers 1989, 1993; Bull and Holthausen 1993; Freedman et al. 1996; Bonar 2000).

Because of the specialized need of cavity-users for critical habitat, they are often considered indicators of the ecological sustainability of forest management (Angelstam and Mikusinski 1997). It is particularly important to maintain the habitat used by "keystone" primary excavators, such as older heart-rotten trees and snags, because a diverse group of secondary users depends on the cavities they create (Freedman et al. 1996; Martin and Eadie 1999). The Pileated Woodpecker (*Dryocopus pileatus*) is one example of a keystone excavator whose abandoned cavities are used by other species for nesting or roosting (Bull and Jackson 1995; Bonar 2000).

The effects of forestry on cavity-users are relatively wel known for forest types of the eastern and northwestern United States (Raphael and White 1984; DeGraaf and Shigo 1985; Zarnowitz and Manuwal 1985; Renken and Wiggers 1989; Connor et al. 1994). However, much less information is available on which to base management decisions in the north-temperate and boreal regions of eastern Canada. This deficiency is important because habitat needs of cavity-nesters vary geographically and are likely to be different in boreal and Acadian forest than in other regions and biomes (Parker et al. 1999). In recognition of this dearth of information, studies were initiated in the mid-1990s of cavity-nesting birds in eastern Canada, with the intent of informing management guidelines to conserve their populations (Doyon et al. 1999; Naylor et al. 1999; Bonar 2000; Flemming et al. 2000). This advice is greatly needed, because of the increasing areas of natural forest that are being intensively managed for timber production in eastern Canada.

Within this context, our study examines effects of forestry on cavity-dependent birds in a region of Acadian forest in southern New Brunswick. We assessed the degree to which cavity-nesting birds use conifer plantations and less-intensively managed stands, compared with natural forest. This was done by conducting breeding surveys of these habitats and by comparing occupancy of nest boxes as an indicator of limitation by natural cavities.

Study Area

The study area is in southeastern New Brunswick, Canada. It is located in the Atlantic Maritime Ecozone (Ecological Stratification Working Group 1995), within the Fundy Plateau Ecodistrict of the Acadian Forest Region (Loucks 1962; Rowe 1972). The climate is humid temperate and the natural forest is dominated by mixed-species stands of Red Spruce (*Picea rubens*), White Spruce (*P. glauca*), Balsam Fir (*Abies balsamea*), Sugar Maple (*Acer saccharum*), Red Maple (*A. rubrum*), Yellow Birch (*Betula alleghaniensis*), White Birch (*B. papyrifera*), and Mountain Birch (*B. cordifolia*). Extensive natural disturbances, including irruptions of native Spruce Budworm (*Choristoneura fumiferana*), have affected the natural forest, which tends to have a mixed-species canopy with gap-phase regenerating patches. Superimposed on the natural disturbance regime is a complex of anthropogenic influences. This began with the selective harvesting of large trees for lumber and ship-building, followed by extensive deforestation for agricultural development, then abandonment of most poorer-quality farmland beginning in the 1920s, and more recently the widespread establishment of conifer plantations.

Our study area is within the Greater Fundy Ecosystem (GFE), a region consisting of Fundy National Park and its surrounding area. The GFE was defined to study ecological consequences of the insularization of Fundy National Park, a 204 km^2 protected area embedded within a landscape whose matrix is being transformed by the conversion of natural forest into conifer plantations (Woodley et al. 1993, 1998; Freedman et al. 1994). The GFE itself is within the Fundy Model Forest (FMF), one of ten "model forests" established to demonstrate "sustainable forestry" in Canada. One declared indicator of sustainability in the FMF is that, at the landscape level, native biodiversity must not be compromised by forest management (Parker et al. 1999).

Methods

Stand selection

We selected 18 stands for study (see Table 1), including representative natural (or "reference") forest and habitats resulting from various intensities of management, including:

- five reference stands of unmanaged mature forest, including three mixed woods (dominated by Red Spruce (*Picea rubens*), Balsam Fir (*Abies balsamea*), and White Birch (*B. papyrifera*), and Mountain Birch (*B. cordifolia*) and two softwood dominated by Red Spruce;
- ten stands that had been clear-cut and then intensively managed to develop conifer plantations ranging from 5 to 19 years in age (the oldest available in the study area); eight were planted with Black Spruce (*Picea mariana*), one with Jack Pine (*Pinus banksiana*), and one with Norway Spruce (*Picea abies*);
- two selectively harvested stands (1-year-old and 12-years-old);
- one 30-year-old naturally regenerated clear-cut.

TABLE 1. General habitat characteristics of stands surveyed for cavity-nesting birds.

Site	Survey Year	Area (ha)	Stand description
Reference mixedwood forest			
Ra	1994	10	mature/mixedwood forest; Red Spruce, Balsam Fir, White Birch
Rb	1995	20	mature/mixedwood forest; Red Spruce, Balsam Fir, White Birch
Rc	1994	10	mature/mixedwood forest; Red Spruce, Balsam Fir, White Birch
Rd	1994	10	mature/Red Spruce-dominated forest
Re	1995	20	mature/Red Spruce-dominated forest
Plantations

P8	1994	10	8-year-old Black Spruce plantation
P9a	1994	10	9-year-old Black Spruce plantation
P9b	1994	10	9-year-old Jack Pine plantation
P15	1995	8	15-year-old Black Spruce plantation with residual snags
P17	1994	10	17-year-old Black Spruce plantation
P18	1995	10	18-year-old Black Spruce plantation
P19	1994	10	19-year-old Black Spruce plantation
Selectively harvested stands			
S12	1995	20	12-year-old selection harvested stand
S1	1995	20	1-year-old selection harvested stand
Naturally regenerated clear-cut			
NR30	1995	20	30-year-old naturally regenerated clear-cut with residual snags

Note that selected study stands were not always paired because of the lack of availability of suitable stands that were given the same management. The study plots affected by forestry were essentially operational stands embedded in a dissimilar habitat matrix generally of mixed-wood forests, and they were surveyed in their entirety. The reference plots were of a size and shape comparable to forestry-affected plots. The study stands were no more than 20 km from each other. Fieldwork was done during 1994 and 1995.

Habitat description

Trees (≥5 cm diameter at breast height (DBH) and >1.5 m tall) and snags (standing dead trees) were sampled in twelve quadrats (20 m × 20 m) arranged as a grid across the study plot. However, in plantations 15 years and older, smaller quadrats (10 m × 10 m) were used because of the uniform structure of tree-sized vegetation. Shrubs (<5 cm DBH) were measured for diameter at 25 cm in two 5 m × 5 m sub-quadrats in opposite corners of each tree-quadrat. Length and diameter of coarse-woody debris (CWD; >5 cm diameter) were also measured in tree-quadrats. The field data were used to calculate the average DBH and basal area by species, including snags, and the volume of CWD.

The cover of species of ground vegetation was determined in 30 randomly located 1 m^2 quadrats per site. The cover of overhead canopy was estimated as the percentage area obscured by foliage when sighting upward through a 4.2-cm diameter cylinder. Here we present summary information; detailed data on woody habitat are in Flemming and Freedman (1998) and on ground vegetation are in Veinotte et al. (2004).

Abundance of birds

Cavity-nesting birds were surveyed by modified spot-mapping to identify territories (Bibby et al. 1999). Habitat use was designated as "nesting territory" if we found evidence of a nest, and as "present" if a nest site could not be located. The surveys were conducted in plots with areas of 8 to 20 ha (Table 1). Ten stands were surveyed in 1994 and eight in 1995, and each was examined seven times from early June through to early July. The locations of calling or singing male birds were mapped in the study plots and also in adjacent habitat, and territorial boundaries were estimated using standard spot-mapping procedures (Bibby et al. 1999). Where possible, we recorded the sex, age (adult/juvenile), and relevant activity (nesting, feeding young, foraging, drumming, singing, calling) of individuals. This information contributed to the assignment of breeding territories.

Nest-box survey

To indicate whether cavities were a limiting factor for dependent species, we installed arrays of 12 nest boxes in each of seven plantations and three reference stands. The nest boxes were made of sections of White Cedar (*Thuja occidentalis*) with natural heart rot and were divided into three sizes: small (3.5-cm diameter entrance hole; ca. 6.5-cm internal width by 16 cm height), medium (6-cm hole, 11 × 34 cm), and large (9-cm hole; 15 × 48 cm). Because the site location and orientation of the entrance hole can affect occupancy (Rendell and Robertson 1994), these factors were standardized. Each nest box was mounted on an aspen pole supported by three steel cables fixed to

rebar pegs, and was placed at a predetermined height (small cavities at 2.5 m, medium at 3 m, and large at 5 m) with the entrance hole facing south. A total of 12 nest boxes was placed in each stand; two of each of size were positioned at 30 m and again at 100 m from a stand edge. The nest boxes were surveyed seven times during each of the 1994 and 1995 breeding seasons, and once late in the summer. We recorded the numbers of eggs, hatchlings, and fledglings of any species occupying the boxes, as well as roosting birds and non-avian species.

Data analysis

Because the study plots were unique habitats in terms of location, site and habitat attributes, and disturbance history, they were not treated as true statistical "replicates" (Hurlbert 1984; Heffner et al. 1996). Moreover, many of our data did not meet assumptions of normality or homegeneity of variance. Consequently, we restricted our analyses to simple comparisons among classes of habitat types. Relationships among stands were examined using multivariate analyses, with data input being matrices of species abundance by site (Kovach 1995). A cluster analysis was used to identify groupings of stands (or "communities"), using an unweighted pair-group procedure with arithmetic averages (UPGMA; Sokal and Rohlf 1995). Chi-square contingency tests were used to test for differences in occupancy rate of nest boxes between (a) unmanaged and managed stands and (b) boxes located at 30 m or 100 m from a forest edge.

Results and Discussion

Habitat

The stands of natural (reference) forest had a large basal area (an indicator of biomass) of trees compared with the other habitats studied (Table 2). Although a high tree density occurred in older plantations and the naturally regenerated site, these were smaller trees than in natural forest. The species composition of the natural forest was mixed, whereas the plantations are more strongly dominated by the planted conifer species. The natural forest also had relatively abundant snags. Of the various managed stands, only the 7-year-old and 15-year-old plantations (P7 and P15, respectively) had many snags, because the pre-harvest snags had not all been removed or felled during the clear-cut, and a subsequent herbicide treatment killed surviving hardwood trees. The 30-year-old naturally regenerated clear-cut also had abundant snags, as did the 12-year-old selectively harvested site. Coarse-woody debris was abundant in the stands of reference forest, where it originated as natural deadfall. Coarse-woody debris was also abundant in the plantations and selectively harvested stands, where it mostly originated as logging slash and, in older plantations, trees cut and left during a non-commercial thin. Similar but more detailed observations have been made by other studies of natural forest and plantations in our study area (Flemming and Freedman 1998).

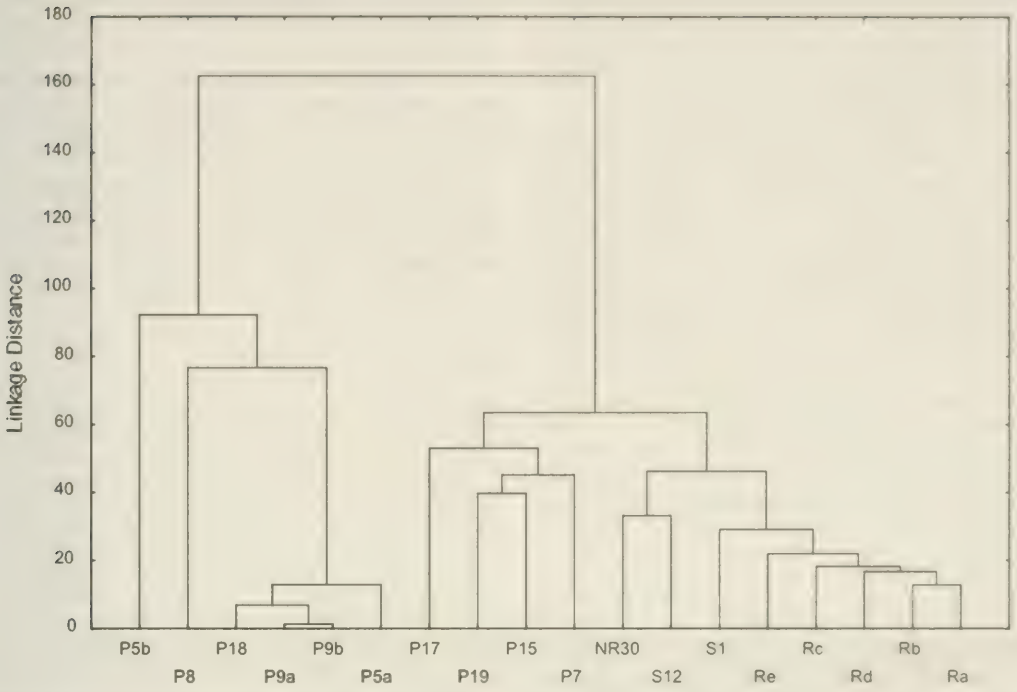

FIGURE 1. Cluster analysis of stands based on their species and abundances of cavity-nesting birds. See Table 1 for explanation of site codes.

The abundance and cover of shrubs and ground vegetation were highly variable among stands (Table 3). In general, these vegetation elements were more abundant in the plantations and other harvested stands, which were in younger stages of secondary succession than the more mature natural forest. Similar, but more detailed observations of forest and plantations in our study area have been made by Veinotte et al. (2004).

Cavity-nesting Birds

A total of 16 species of cavity-nesting birds was observed (Table 3). The most abundant species were the Black-capped Chickadee (24% of the territories; see Appendix 1 for avian binomials), Boreal Chickadee (23%), Red-breasted Nuthatch (16%), and Winter Wren (14%). The species richness was higher in the natural forest (average of 10.0 species per stand; total of 14 species present in the habitat type) than in plantations (2.3/stand; 8 species present), selectively harvested stands (7.0/stand; 9 species present), or the naturally regenerated clear-cut (5.0/stand). Abundance was also higher in the reference forest (average 5.3 territories/10 ha) than in plantations (1.0/10 ha), selectively harvested stands (3.8/10 ha) or the naturally regenerated clear-cut (2.5/10 ha). Among the ten plantations studied, the highest density of cavity-nesting birds was in P15 (4.0 territories/10 ha), which also had a relatively large number of snags (2.1 m^2/ha compared with an average of 0.4 m^2/ha among the other nine plantations).

A cluster analysis segregated the "community" of cavity-nesting birds of the natural forest from those of the other treatments (Figure 1). In the cluster analysis, the five reference stands were arranged together on the right-hand side. The selectively harvested stands (S1 and S12) and naturally regenerated stand (NR30) had relatively abundant cavity-nesting birds and clus-

Red-breasted Nuthatch	*Sitta canadensis*
Wood Duck	*Aix sponsa*
Winter Wren	*Troglodytes troglodytes*

tered close to the reference stands. Of the plantations, those with relatively abundant and species-rich cavity-nesting birds clustered together (i.e., P7, P15, P19, and P17), while the most depauperate ones formed another cluster (i.e., P5b, P8, P9a, P9b, P5a).

The observation that cavity-nesters are more abundant in mature mixedwood forest than in harvested stands or plantations is consistent with research elsewhere, although the specifics vary depending on the forest region and species of birds present (e.g., Raphael and White 1984; DeGraaf and Shigo 1985; Zarnowitz and Manuwal 1985; Hansen et al. 1995; Kirk and Naylor 1995; Niemi et al. 1998; Hobson and Bayne 2000).

Of the 16 species of cavity-nesting birds recorded during our study, eight were not recorded in any of the plantations: Saw-whet Owl, Barred Owl, Yellow-bellied Sapsucker, Downy Woodpecker, Black-backed Woodpecker, Pileated Woodpecker, White-breasted Nuthatch and Winter Wren. One species, the Tree-Swallow, was only recorded as breeding in plantations in which nest boxes were present.

Nest-box Occupancy

Nest boxes were used by five species for nesting and by four for roosting (Table 4). Tree Swallow accounted for 41% of the nests, American Kestrel 31%, and Boreal Chickadee 17%. The most frequently roosting species were Tree Swallow (48%) and Northern Flicker (33%). The use of nest-boxes for nesting was much greater in plantations (average 4.0/10 ha) than in the natural forest (0.3/10 ha), and similarly for roosting (average 2.9/10 ha in plantations and 0.3/10 ha in reference stands). Overall, 33% of the nest boxes in plantations were used for nesting or roosting (28 of 84 boxes with nests), compared with only 3% in natural forest (1 of 36 boxes with nests). These observations support the notion that suitable cavities are a limiting factor in plantations in the study area, compared with the natural forest. The plantations we studied appear to provide suitable habitat for foraging and other purposes, but can only be used for nesting and roosting by cavity-dependent birds if their need for cavities is met. There were no recorded cases of a failed nest in the nest boxes.

Of the 28 nest boxes used for nesting in plantations, 7.5% were located 30 m from an intact forest edge and 15.8% were 100 m from such an edge (marginally significant difference; $\chi^2 = 3.78$, 1 df; $>0.05 < P < 0.1$). The apparent reluctance to use nest-boxes located closer to a habitat edge may be associated with a greater risk of predation (Paton 1994; Derochers and Hannon 1997).

Implications for Management

It appears that conifer plantations in our study region can recover bird populations rather quickly after establishment, but the species composition is different from that of natural forest, and cavity-dependent species are present in low abundance (Freedman et al. 1994; Freedman and Johnson 1999; Johnson and Freedman 2002). Moreover, observations and models of stand development suggest that intensively managed plantations are depauperate in snags, cavity-trees, and coarse-woody debris and are likely to remain so over subsequent rotations because the harvesting removes all large-dimension tree biomass (Flemming and Freedman 1998). These changes do not augur well for cavity-dependent species in stands and landscapes extensively converted into forestry plantations.

Clearly, the extensive conversion of mixedwood Acadian forest into conifer plantations will result in a decline in the abundance and species richness of cavity-dependent birds at the scales of both stand and landscape. Certain site mitigations might help some species, particularly the retention of some snags and large living trees within plantations, or much less preferably, the provision of nest boxes to provide local nesting and roosting habitat (Welsh and Capen 1992; Newton

TABLE 5. Use of nest boxes in plantations and reference forest during two study years. Each site had an array of 12 nest boxes, each made of a section of a hollow log of White Cedar. All plots were 10 ha in area. Note some stands from Table 3 had no nest boxes installed, so the number of stands differs between Table 3 and 4.

1994; Flemming et al. 2000). It is likely, however, that these site mitigations will not be sufficient to maintain some cavity-dependent species, particularly those with large home ranges that encompass a mosaic of habitat patches, such as Pileated Woodpecker (Bonar 2000; Flemming et al. 2000). These species will require large protected areas of unmanaged forest to function as population centres.

Without sympathetic management of this sort, it is likely that the population viability of some cavity-dependent birds in regions extensively managed for forestry will become compromised. Some jurisdictions have established guidelines to help these species — in New Brunswick, for example, timber companies operating on Crown Land are to required to retain at least 10% of conifer-dominated forest in mature or older successional stages, in patches of 500 or more ha (Sullivan 1996). However, these requirements may not be adequate to maintain critical habitat for all species of cavity-nesting birds, particularly keystone primary excavators (Flemming et al. 2000). It is essential that these conservation guidelines be monitored to ensure they achieve their intended ecological purpose, including the maintenance of viable populations of all cavity-dependent species. In the meantime, a precautionary approach to ecologically sustainable forestry would require that additional large areas of natural forest be set aside from intensive economic use, as parks or other kinds of protected areas.

Acknowledgments

We are grateful to staff at Fundy National Park for logistical support. We thank Irving Forest Products Ltd. for allowing access to their plantations and for providing poles and cedar sections for constructing nest boxes. Research funding was provided by the Fundy Model Forest, Natural Resources Canada, Parks Canada, and the Natural Sciences and Engineering Research Council of Canada.

Recent Invasion, Current Status and Invasion Pathway of European Common Reed, *Phragmites australis* subspecies *australis*, in the Southern Ottawa District

PAUL M. CATLING[1] and SUSAN CARBYN[2]

[1]Biodiversity, National Program on Environmental Health, Agriculture and Agri-food Canada, Wm. Saunders Building, Central Experimental Farm, Ottawa, Ontario K1A 0C6 Canada; e-mail: catlingp@agr.gc.ca

Catling, Paul M., and Susan Carbyn. 2006. Recent invasion, current status and invasion pathway of European Common Reed, *Phragmites australis* subspecies *australis*, in the southern Ottawa district. Canadian Field-Naturalist 120(3): 307–312.

A survey of populations of native North American Common Reed (*Phragmites australis* subsp. *americanus*) and the introduced invasive alien, European Common Reed (*Phragmites australis* subsp. *australis*) was conducted in four eastern Ontario townships in 2003. The historical status of the two taxa in the region was evaluated through reference to herbarium specimens collected over the past century. The introduced subspecies appears to have entered the district in the 1970s and subsequently assumed dominance but was not recognized as an alien until 2003. It is now widespread in the four townships where ninety-five populations were recorded during the 2003 survey. Of these, 25 were referable to the native subspecies which was localized and 70 were referable to the introduced subspecies which was widespread. The native subspecies occurs in natural wetlands and also spreads to roadsides, but the introduced subspecies is much more strongly associated with roads, where the rhizomes extend onto gravel shoulders and are broken and transported by construction equipment, graders, ploughs, mowers, and in the treads of many kinds of vehicles. Sensitive wetlands should have buffer zones exceeding 1000 m to prevent colonization of subsp. *australis*. Monitoring of the two subspecies will be essential to the protection of native biodiversity, since early detection of the alien subspecies in a sensitive wetland will offer the best opportunity for control.

Key Words: North American Common Reed, *Phragmites australis* subsp. *americanus*, European Common Reed, *Phragmites australis* subsp. *australis*, invasion pathway, alien, invasive species, Ottawa, Canada.

One of the most productive plants in temperate regions, Common Reed, *Phragmites australis* (Cav.) Trin. *ex* Steud. has economic and agricultural values and is under-exploited (Small and Catling 2001). Domestication and introduction of non-native races however, pose some potential risks to both agriculture and environment. It is a major pest of irrigation and flood control channels in some parts of the world and, being able to grow in water 2 m deep or on dry ground, it is not readily controlled by drawdown.

It was only recently realized that both native and introduced races existed in North America (Catling et al. 2003). The native plants have been designated subspecies *americanus* Saltonstall, P. M. Peterson & Soreng (Saltonstall et al. 2004) and the introduced plants identified as subspecies *australis* (Catling 2006, 2007, Catling et al. 2007). It is believed that the introduced subspecies *australis* originated from southern Europe. It has been recently recognized as a major threat to North American biodiversity (Chambers et al. 1999; Meyerson et al. 2000; Catling et al. 2003; Robichaud and Catling 2003; Catling 2005). In a recent survey of the St. Lawrence River wetlands it was found to have a greater impact on native plant diversity than most other invasive aliens including Purple Loosestrife, *Lythrum salicaria,* (Lavoie et al. 2003). The subspecies *australis* is currently spreading in Canada from areas of concentration in southern Ontario and southern Quebec and has only recently been reported from western Canada (Martin 2003; Schueler et al. 2003) and the maritime provinces (Catling et al. 2004).

In eastern Ontario the alien subspecies *australis* was first recognized in 2003, but it apparently invaded the area a few decades earlier. Local botanists noticed the rapid spread of dense stands of *Phragmites* beginning in the 1970s and the rapid change from the status of a locally rare plant (Dore 1959) created suspicion about the possibility of an introduced race. Preliminary observations suggested that it spread into the region along roads very recently and became widespread. Here we analyse its apparent recent spread into the region along roads by providing information on its history of invasion, current status and invasion pathway in the southern part of the Ottawa district based on identification of herbarium specimens and a current survey of populations in four adjacent townships. This work will also provide benchmark data for analysis of future changes in status of native and introduced subspecies, thus contributing information needed to predict rate of spread and impact.

Methods

A recent study of plants of *Phragmites australis sensu lato* in eastern Ontario suggested that plants with lower glumes exceeding 4.2 mm long were referable to the native subspecies *americanus* (Robichaud and Cat-

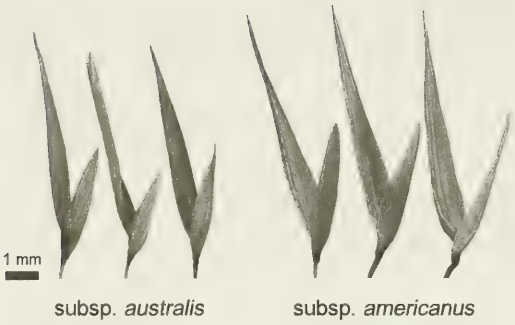

FIGURE 1. Glumes of *Phragmites australis*. The smaller on the right of each attached pair is the lower glume, whereas the longer glume on the left of each pair is the upper glume. The subspecies *australis* on the left has shorter lower glumes as represented by three examples from an inflorescence of a specimen from Dundas County (*Catling and Robichaud*, 10 Oct. 2002, DAO). On the right are three pairs from an inflorescence of subspecies *americanus* from Leeds and Grenville County (*Catling and Kostiuk*, 30 Aug. 2003, DAO) showing its characteristically longer lower glumes.

ling 2003). More recent work based on correlation with basal stem color and date of collection (Saltonstall et al. 2004; Catling and Mitrow *in press*) has supported the separation using 4.2 mm for length of longer glumes, this separation being correct (i.e. correlated with other diagnostic features) 97.3% of the time (Figure 1). Most recently (Catling 2006) the following key has been recommended for distinguishing the two subspecies:

Basal internodes red or reddish-purple; longer lower glumes 3.8-7 mm long . . . . . subspecies *americanus*

Basal internodes pale yellow; longer lower glumes 2.6-4.2 (4.8) mm long . . . . . subspecies *australis*

For the study reported here undertaken in 2003, we used a length of 4.2 mm or more to identify the native subspecies *americanus* and 4.1 mm or less to identify the introduced subspecies *australis* in a survey of four adjacent geographic townships (Figure 2): Russell (45.2833°N, 75.2833°W), Osgoode (45.2333°N, 75.5000°W), North Gower (45.1500°N, 75.6833°W) and Marlborough (45.0666°N, 75.8166°W). Hybrid-like or intermediate clones were not observed during this study but several were located subsequently in townships to the north.

The survey was conducted in May 2003 at which time the persistent flowering stalks of the previous year were readily visible on the landscape and the persisting inflorescences were not so damaged as to prevent measurement of first glume lengths. The survey included driving all roads in each township, checking known locations and searching larger open wetlands in Rideau Township on foot. All small wetlands visible from roads were examined with binoculars. Location of populations was recorded with GPS and size of patches and number of flowering stalks and distance from road were also recorded. Populations were defined as less than 500 m apart or 500 m in length. A voucher inflorescence from one of the tallest flowering stems was collected from each population and from these vouchers the length of the longest first glume of 25 examined was recorded. Voucher specimens for some the collections were deposited in the AAFC [Agriculture and Agri-Food Canada] vascular plant collection (acronym DAO ["Department of Agriculture, Ottawa"]). All flowering culms within individual stands were similar and were assumed to represent single clones.

Collections in Canadian herbaria from Ottawa area and Carleton and Prescott counties were identified to race (using criteria described above) in order to determine status of the two subspecies in the region in the past. The historical information was compared to maps of the occurrence of the native and introduced

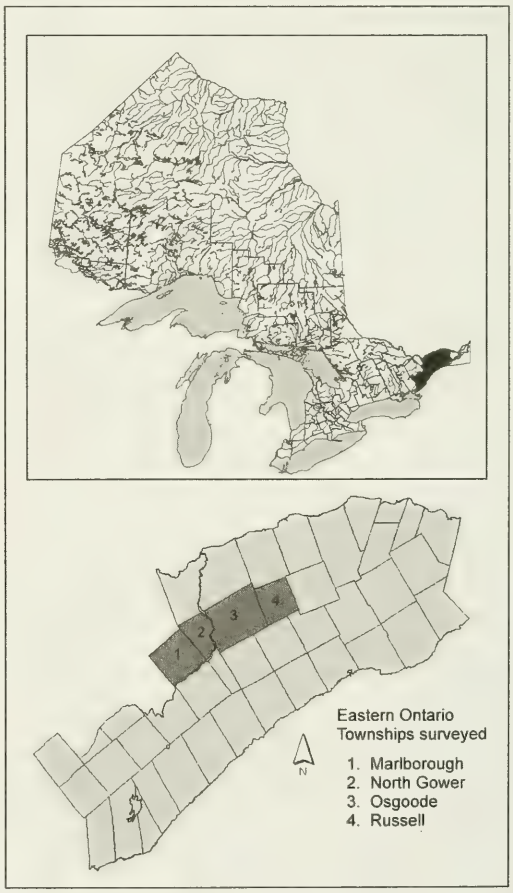

FIGURE 2. Location of four adjacent townships in eastern Ontario where native and introduced subspecies of *Phragmites australis* were surveyed and mapped in May 2003. Inset map above shows eastern Ontario and Great Lakes with Eastern Ontario region shown in black.

subspecies in the four townships based on the results of the 2003 survey.

The relationship to roads was analysed by comparing the distribution of both subspecies by plotting on township maps showing roads using histograms showing frequency of various distances from roads. In order to further elucidate the history of spread, the size of patches was compared on major and minor roads, all at least 20 years old, in Russell township.

Results

History of Invasion

In Canadian herbaria there are 45 specimens of *Phragmites australis* collected in the southern portion of the Ottawa district (Ottawa-Carleton Regional Municipality and Prescott-Russell counties). Of these, 21 collected prior to 1970 are referable to the native subspecies. The earliest collection of the introduced subspecies was in 1976 at Manotick (*Hanes*, DAO). Of the 24 specimens collected after 1970, only five are referable to the native subspecies, the remainder having the relatively short first glumes of the introduced subspecies. Thus the introduced subspecies appears to have entered the district in the 1970s and subsequently assumed dominance but was not recognized as an alien until 2003 (Catling et al. 2003).

Present Status

Ninety-five populations were recorded in the four townships during the 2003 survey. Of these, 25 were referable to the native subspecies and 70 were referable to the introduced subspecies. Both subspecies

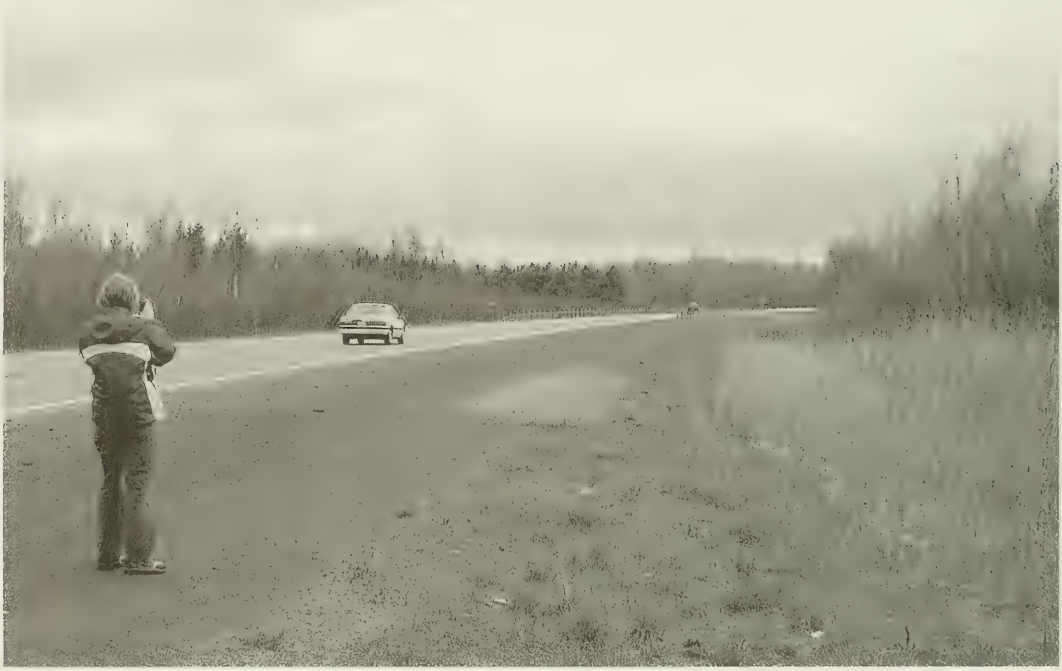

FIGURE 4. Patch of pale stems of *P. australis* subsp. *australis* on gravel portion of a roadside and extending in a large clone in the adjacent ditch and swamp. Highway 417, Russell Township, May 2003.

occurred in all four townships, but the native subspecies was much more localized, with most populations in a single wetland (Figure 2).

Invasion Pathway

As seen in the distribution maps (e.g. Figure 3) there is a strong association of the introduced subspecies with roads (Figure 4). This is confirmed in the histogram (Figure 5) where the vast majority of the populations of the introduced subspecies are within 100 m of a road. In fact 52% were in the roadside gravel (Figure 4) and 84% were within 3 m of the boundary between vegetation and gravel shoulder. Populations of the native subspecies occurred at greater distances from a road (Figure 5) with 36% on the shoulder and 60% within 3 m. Although occurrence of the native subspecies on roadsides was much less, it is clearly spreading from natural habitats to roadsides. Since both subspecies may come into close contact on roadsides, there is an opportunity for the subspecies to hybridize. The introduced subspecies was most frequent in the eastern townships that have the most roads (Figure 3). The native subspecies was most frequent in the far western township which has the least extensive road network and the most extensive natural wetlands.

Major concentrations of the introduced subspecies occurred along Highway 417 (upper right in Figure 3), the busiest and oldest major highway in the region, and the largest patches in Russell township occurred along this road, suggesting that this is one of the places where it first entered the region (Figures 3 and 6). The association of the introduced subspecies with roads suggested spread by dispersal of rhizomes by road vehicles rather than wind-blown seed which would have resulted in more occurrences at greater distances from roads. The tough rhizomes extend into the gravel shoulders and even onto the asphalt (Figure 4). They are readily broken and transported by ploughs, graders and in the tire treads of many kinds of vehicles (personal observation). This mechanism of dispersal is believed to be largely responsible for the rapid spread and present strong association with roads.

There is a possibility that spread along roads is facilitated by relatively high sodium salt (NaCl) concentrations, as noted for many other vascular plants spreading along roadsides (e.g. Catling and McKay 1980, 1981; Reznicek and Catling 1987). Salt concentrations may reduce competition by eliminating other species, thus promoting salt-tolerant species. Although the alien subspecies may be tolerant of relatively high salt concentrations, reliance on salty habitats is probably much less than for other rapidly spreading roadside plants such as *Carex praegracilis* (e.g., Reznicek and Catling 1987). Some patches of the alien subspecies of Common Reed do occur at great distances from roads and some roadside patches extend up to 100 m from roads beyond the influence of sodium salt.

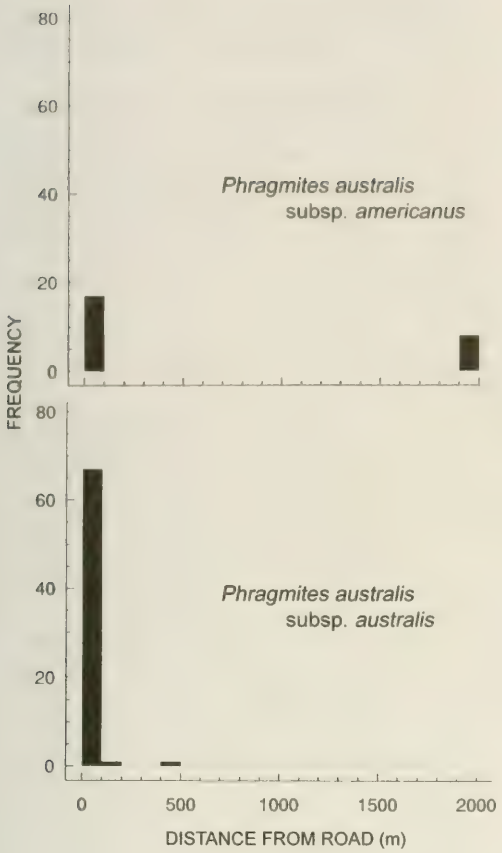

FIGURE 5. Histograms showing frequency of distances from major and minor roads of native and introduced subspecies of *australis* in four eastern Ontario townships.

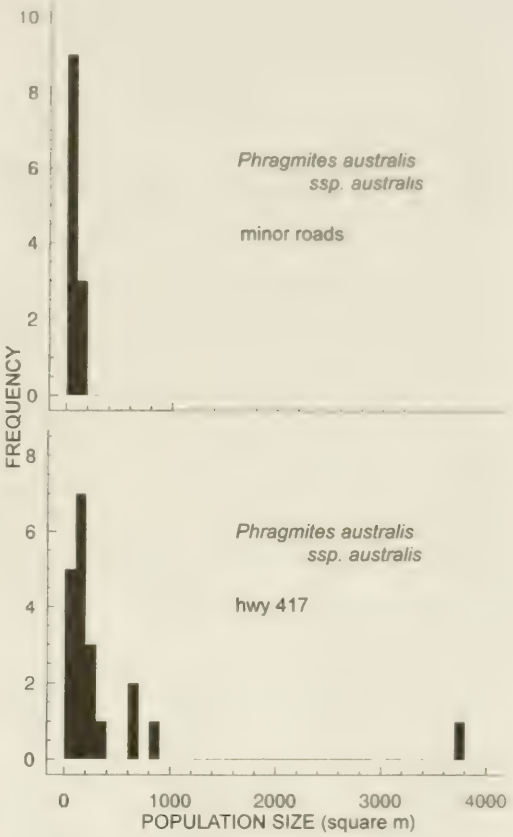

FIGURE 6. Histograms showing frequency of clone sizes of the introduced *Phragmites australis* subspecies *australis* in relation to major and minor roads in Russell Township.

Further evidence for a lack of strong dependence on sodium salt is the observation that the alien subspecies of Common Reed occurred along many minor and gravel roads that do not receive applications of deicing salt.

The introduced subspecies has colonized two natural wetlands in the study area without spreading from a roadside. One of these stands is 500 m from a road along a pond shore used extensively as a staging area by waterfowl. This colonization may have been the result of transport of rhizomes by the waterfowl, which occurs with many aquatic plants, but is unusual. Once in a wetland system the rhizomes are likely to be transported further by aquatic mammals and birds for building habitations, platforms and nests. Successful germination of wind-dispersed seed is also a possibility, but strong association with roads suggests that it happens infrequently. Both native and introduced populations produce apparently viable seed with quantities varying between poplulations (personal observation, Catling). As alien Common Reed increases on the landscape the frequency of unusual dispersal mechanisms is likely to increase, and spread through wetlands may increase substantially.

Future Spread

Considering that it is being spread by road vehicles along corridors of essentially continuous habitat, including new and disturbed habitats, the rate of spread can be anticipated to be rapid. *Carex praegracilis* W. Boott is believed to have spread the same way throughout much of eastern North America from the midwest in only 30 years (e.g., Reznicek et al. 1976; Reznicek and Catling 1987). Since the introduced subspecies of *Phragmites australis* has apparently spread from roadsides to distances of up to 500 m from roads (Figure 5), it appears that it is not confined to the near road environment. Although it seems less likely that the introduced subspecies will invade sensitive wetlands through introduction by waterfowl, the chances will increase as it becomes more abundant. There are also

opportunities for spread into isolated wetlands through transport along tracks of off-road vehicles including motorcycles, ATVs and snowmobiles.

The introduced subspecies has extensively spread into both saline and non-saline wetlands and along both dry and wet roadsides in parts of the United States. Within another 10-20 years it is expected to line many major roadways in eastern Canada and it will have entered many wetlands from adjacent or nearby roads. As it spreads it is most likely to become established first along major roads, providing an early warning of future impact on the nearby landscape.

The introduction of invasive aliens into wetlands by roads provides another reason to have extensive buffer zones around wetlands with high protection priority. Considering that the vegetative spread of *P. australis* can be very rapid, and mammals and birds transport rhizome fragments over substantial distances for nesting, buffers exceeding 1000 m are desirable. Monitoring of the two subspecies will be essential to the protection of native biodiversity, since early detection of the introduced subspecies in a sensitive wetland will offer the best opportunity for control.

Kuzyk, Gerald W., Jeff Kneteman, and Fiona K.A. Schmiegelow. 2006. Pack size of Wolves, *Canis lupus*, on Caribou, *Rangifer tarandus*, winter ranges in westcentral Alberta. Canadian Field-Naturalist 120(3): 131–318.

We studied pack size of Wolves (*Canis lupus*) on Woodland Caribou (*Rangifer tarandus caribou*) winter ranges in westcentral Alberta. These Caribou winter ranges are experiencing increasing pressure from resource extraction industries (forestry, energy sector) and concerns have been raised regarding increased Wolf predation pressure on Caribou in conjunction with landscape change. Thirty-one Wolves, from eight Wolf packs, were fitted with radiocollars on two Caribou winter ranges in the Rocky Mountain foothills, near Grande Cache, Alberta (2000-2001). There was a mean of 8.2 Wolves/pack and between 30 and 39 Wolves on each of the RedRock/Prairie Creek and Little Smoky Caribou ranges. The average pack size of Wolves in this region does not appear to have increased over that recorded historically, but the range (5-18) in the number of Wolves per pack varied considerably over our study area. Wolves preyed predominately on Moose (*Alces alces*), averaging one Moose kill every three to five days. There was some indication that pack size was related to prey size, with the smallest pack preying on Deer (*Odocoileus* spp.). It was clear that Caribou could not be the primary prey for Wolves, due to their low numbers, and relative to the pack size and Wolf kills we observed.

Key Words: Wolf, *Canis lupus*, Caribou, *Rangifer tarandus*, Moose, *Alces alces*, White-tailed Deer, *Odocoileus virginianus*, predation, pack size, colour phase, kills, Alberta.

Pack size of Wolves (*Canis lupus*) can provide an important indication of ungulate abundance (Fuller 1989; Schmidt and Mech 1997; Hayes et al. 2003) and human impacts on the landscape (Mech 1995). The number of Wolves in each pack can be related to prey availability (Fuller 1989) and may be regulated by dispersal, pup survival and disease prevalence (Mech 1970; Mech et al. 1998). The amount of food available to each Wolf has been inversely related to pack size (Thurber and Peterson 1993; Schmidt and Mech 1997), with smaller pack sizes found in areas of low ungulate density (Messier 1985). In contrast, pack size may remain stable when the amount of food per Wolf decreases, possibly due to a genetic advantage for the breeding pair when sharing limited food with their offspring (Schmidt and Mech 1997). Maximum Wolf pack size may be regulated by behaviors within the pack, such as social dominance, which can facilitate dispersal. Pack size has also been related to prey size. Average pack size of Wolves hunting White-tailed Deer (*Odocoileus virginianus*) is generally less than seven (Mech 1970; Fuller 1989), whereas packs preying on Moose (*Alces alces*) are generally larger, having ten or more Wolves per pack (Peterson et al. 1984; Mech et al. 1998; Hayes et al. 2003). Vucetich et al. (2004) demonstrated that larger packs are better able to compete with ravens and do accrue a foraging advantage. Reports of large Wolf Packs with over 20 members have been documented in regions where there is little Wolf harvest (Hayes and Harestad 2000) or in protected areas (Carbyn et al. 1993; Peterson 1995; Mech et al. 1998; Smith et al. 2004).

Predators may negatively affect endangered prey species when landscapes become impacted by human disturbance (Schneider 2001). Landscapes in westcentral Alberta are facing increased pressures from forest harvesting and the energy sector (oil and gas). Forest harvesting may alter the movements and distribution of Wolves (Kuzyk et al. 2004) and ungulates (Smith et al. 2000), and in combination with linear corridors (roads, seismic lines) from oil and gas activities, can enhance human access to once remote areas and possibly increase human-caused Wolf mortality from shooting and trapping. Enhanced predation by Wolves, facilitated by landscape change such as increased travel efficiency on linear corridors (James and Stuart-Smith 2000) and associated increases in alternate prey populations (James et al. 2004), is thought to be the primary factor for Caribou declines in Alberta (Edmonds 1988; McLoughlin et al. 2003). In Alberta, Woodland Caribou (*Rangifer tarandus caribou*) are classed as a threatened species under the provincial Wildlife Act and on the Species at Rist Act Public Registry [SARA, http://www.sararegistry.gc.ca/species/SpeciesDetails_e.cfm?sid=636] and special management considerations are necessary to maintain numbers and habitat (Edmonds 1998; Dzus 2001). More information is required on Wolf populations, such as pack sizes, to be better able to predict long-term changes in the dynamics of Wolves and Caribou associated with land-

scape change (Weclaw and Hudson 2004). The objective of this paper is to present current information on pack size and associated predation by Wolves that can be used in decision-making processes for long-term Caribou conservation.

Study Area

The study area is approximately 5000 square kilometres, located in the foothills of west-central Alberta, near the town of Grande Cache (54°N 119°W). The area is classed into subalpine and boreal natural subregions (Beckingham and Archibald 1996), and contains several main rivers but lakes are scarce. Elevations range from 1300-1800 metres, and the climate is subarctic, with short wet summers and long cold winters. Temperatures average 16°C in July and -13.5°C in December (Beckingham and Archibald 1996). The forests are primarily Lodgepole Pine (*Pinus contorta*) and some White Spruce (*Picea glauca*). The wetlands support mostly Black Spruce (*Picea mariana*) and some Tamarack (*Larix laricina*). Some south facing slopes have Aspen (*Populus tremuloides*) and willow (*Salix* sp.).

The study area contains three major Caribou herds: the Red Rock/Prairie Creek and Al La Peche are mountain herds and represent a migratory ecotype, while the Little Smoky herd is boreal or sedentary ecotype (Edmonds 1988). Population size for the mountain herds is estimated at 600-750 Caribou (Edmonds 1998), and the Little Smoky herd is estimated at fewer than 100 animals (Smith 2004). The study area also supports a high diversity of other large mammals. Moose are found at densities ranging from 0.12 to 0.25 Moose per square kilometer (Alberta Fish and Wildlife unpublished data). Other ungulates occurring in the area are Elk (*Cervus elaphus*), Mule Deer (*Odocoileus heminous*), White-tailed Deer, Bighorn Sheep (*Ovis canadensis*), Mountain Goats (*Oreamnos americanus*) and Wild Horses (*Equus cabalus*). Wolves (*Canis lupus*), Coyotes (*Canis latrans*), Grizzly Bears (*Ursus arctos*), Black Bears (*Ursus americanus*) and Cougars (*Felis concolor*) also exist throughout the study area.

Wolf Captures and Monitoring

Wolf captures were conducted on two Caribou winter ranges in the winters of 2000 and 2001. Four Wolf packs were located on the winter range of a migratory mountain Caribou population (Red Rock/Prairie Creek herd) and four packs located on the winter range of a sedentary boreal Caribou population (Little Smoky herd) (Figure 1). Ungulate baits were placed in strategic locations seven to ten days prior to the initiation of the Wolf capture operation, to enhance detection of Wolves. Wolves were located by following trails in the snow from a fixed-wing aircraft (Mech 1966; Mech et al. 1998). All Wolf handling was approved by the Faculty of Agriculture, Forestry and Home Economics Animal Care Policy (Number 96-99D), subject to the protocols of the Canadian Council of Animal Welfare. Wolf captures were accomplished by either helicopter darting (Ballard et al. 1991) or netgunning, then physically restraining the Wolf with restraining forks, and hand-injecting 1-2 mls of telazol at 200mg/ml (Kuzyk 2002). Adults were distinguished from pups by tooth eruption patterns (Van Ballenberghe and Mech 1975) whereas yearlings were classed on subjective physical criteria (size), as there is no definitive method to categorize yearling Wolves (Mech et al. 1998). Adult Wolves were fitted with store-aboard GPS (Global Positioning System) collars (Lotek Engineering Systems, Newmarket, Ontario or Televilt GPS-Simplex, Lindesberg, Sweden) or VHF (Very High Frequency) radiocollars (Lotek Engineering). Pups were fitted with VHF collars only. All Lotek GPS collars were equipped with remote dropoff units, intended to release when signaled from the air. All radiocollared Wolves were relocated by aerial radiotracking (Mech 1974) within one to four days of capture to determine if they had rejoined their packs. Color phases of Wolves were recorded as gray, black, or white following Dekker (1986), and adding a category of blue.

Wolf pack size was recorded during aerial radiotracking in February and March of each year, when pack size would be at a minimum (Mech 1970), thus yielding a conservative estimate. Most packs were intensively monitored in March of 2000, increasing the chances of a good count. The best estimates of Wolf pack size were made when the Wolves were traveling in single file on a linear corridor or river. Lone Wolves were assumed to account for 10% of the total population (Fuller 1989). We did not extrapolate our pack size data to determine Wolf density, due to insufficient temporal data required to adequately determine annual territory sizes. In addition, our broader project objectives entailed studying Wolves in late winter, corresponding with winter range occupancy by migratory Caribou. It is the winter range of these caribou that is currently undergoing industrial development, and thus of primary conservation concern.

Wolf kills were determined during a two-week period in March 2000 by aerially locating radiocollared Wolf packs and finding their ungulate kills (Mech 1974). Flights were conducted twice daily in hopes of detecting Wolf-killed deer (Fuller 1989). When a Wolf pack was located, Wolves were counted and the area searched for ungulate carcasses. A kill was assumed to be caused by Wolves if there were bloodtrails indicating a successful chase and a disarticulated carcass (Hayes et al. 2000). At each kill site, the number and behavior of Wolves were recorded (Mech 1966). All Wolf-killed ungulates that could not be identified to species, gender and age (adult-calf) from the air were later ground inspected.

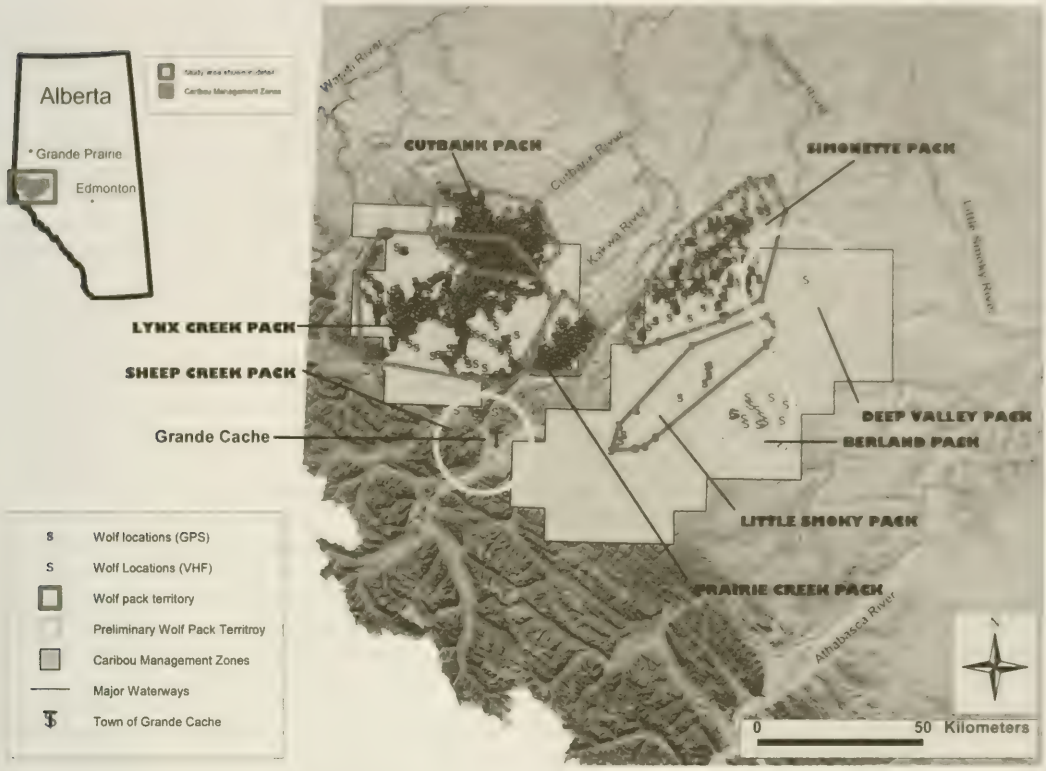

FIGURE 1. Distribution of eight Wolf packs on two Caribou winter ranges in west-central Alberta during 2000 and 2001.

TABLE 1. Sex ratio, age class and color phase of Wolves (n=31) captured in west-central Alberta during 22 January – 13 March, 2000 and 15–17 February, 2001.

Sex Ratio (n=31)	Age Class (n=31)	Color Phases (n=31)
14 Males	15 adults	19 black (61%)
17 Females	8 yearlings	8 gray (26%)
	8 pups	3 white (11%)
		1 blue (2%)

Results

Thirty-one Wolves were captured on two Caribou ranges: 18 captured in 2000 and 13 in 2001 (Table 1). Nine Wolves were aerially darted and 24 were netted (two recaptures). There were no capture-related Wolf mortalities during this study. A total of 16 GPS (14 Lotek and 2 Televilt) and 17 VHF radiocollars were deployed. There were seven known mortalities of radiocollared Wolves (23%) over fifteen months: two were shot and five died of natural or unknown causes. Colors phases of the radiocollared Wolves were 61% black, 26% gray, 11% white and 2% blue.

Eight Wolf packs were located on the two Caribou ranges (Tables 1 and 2; Figure 1). There were between 54 and 77 (mean = 66) Wolves on the Little Smoky and Red Rock/Prairie Creek Caribou ranges, equating

TABLE 2. Pack size of Wolves on the Red/Rock Prairie Creek (RPC) and Little Smoky (LSM) Caribou winter ranges in west-central Alberta in late winters of 2000 and 2001.

Mean	8.2	

TABLE 3. Ungulate kills by Wolf packs in west-central Alberta in March 2000.

Wolf Pack	Days Monitored	Moose kills	Deer kills	Ungulate kills/day
Lynx Creek	9 (Mar 2-10)	2		1/ 4.5
Cutbank	14 (Mar 2-15)	3		1/ 4.7
Simonette	14 (Mar 2-15)	4	2	1/ 1.8

Note: Prairie Creek pack not entered as only one Elk kill was located.

to 8.2 Wolves/pack. Each Caribou range had between 30-39 Wolves with Wolf pack sizes ranging from 5-18 (Table 2). Twelve ungulate kills were recorded from four Wolf packs during 14 days of monitoring in March 2000 (Table 3). Ungulate kills consisted of seven cow and two calf Moose, two deer (unknown species) and one cow Elk. Wolves preyed predominately on Moose, averaging one Moose-kill every three to five days.

Discussion

We recorded a mean pack size of 8.2 Wolves/pack for eight Wolf packs on the RedRock/Prairie Creek and Little Smoky Caribou ranges. This is similar to the 8.7 Wolves/pack averaged over five other Alberta Wolf studies conducted between 1975 and 1985 (Gunson 1992) and marginally higher than the 6.8 Wolves per pack recorded in January 1995 in west-central Alberta during the Yellowstone-Idaho Wolf relocation (Kneteman 1995*). Pack size of Wolves in our study area varied considerably, ranging from 5 to 18 Wolves/pack. The larger Wolf packs (Lynx Creek n = 18; Simonette n = 11) preyed primarily on Moose, whereas the smallest pack (Prairie Creek n = 5) preyed predominately on deer, consistent with results from other nearby studies (Carbyn 1974; Weaver 1994). A confounding factor in estimating numbers of Wolf-killed ungulates in west-central Alberta is the difficulty of detecting Wolf-killed deer (Kuzyk 2002; Kuzyk et al. 2005), due to the small size and cryptic color of deer, and the short time required for Wolves to consume deer carcasses (Fuller 1989). All Wolf packs in this study were observed either hunting deer or at deer kills. During intensive monitoring in March 2000, the Prairie Creek pack was seen hunting deer, and was thought to have made deer kills, but those were never detected from the aircraft. This resulted in somewhat ambiguous information, as data indicate this pack killed only one Elk in nine days of monitoring. But further analysis of GPS data collected during the nine-day monitoring period suggested the Prairie Creek pack had made a minimum of three deer kills (Franke et al. 2006). The importance of deer to Wolves in this study area should not be underestimated. Kuzyk et al. (2005) found Wolves in this study area traveled 4.2 times less when near ungulate carcasses then when away from them, and suggested that Wolf packs preying primarily on deer, as opposed to Moose, may pose a greater predation risk to Caribou due to associated increase travel and encounter rates. Further research to quantify the importance of deer in this Wolf-ungulate system should be initiated such as measuring Wolf encounter rates with deer (Kunkel et al. 2004).

No Caribou kills were detected during this study, probably due to the low numbers of Caribou in the region (Smith 2004) and the short time it takes Wolves to consume a carcass (Hayes et al. 2000). Nevertheless, Caribou could not be the primary prey for Wolves in westcentral Alberta, as the numbers of Caribou could not support the numbers of Wolves we recorded. For example, there are fewer than 100 Caribou in the Little Smoky herd (Smith 2004), and four Wolf packs overlap their range, with each pack killing an estimated 40-85 ungulates each winter.

Humans may impact Wolf pack size when access to remote areas increases, and human-caused mortality to Wolves increases from shooting, trapping and road collisions (Mech 1995). Landscapes in west-central Alberta are being altered by resource extraction industries which have increased human access to previously remote areas. We recorded 23% mortality for radiocollared Wolves over fifteen months, similar to annual mortality rates (20-27%) found in other studies (Pletscher et al. 1997; Mech et al. 1998). This level of mortality is thought to be low and would not influence overall Wolf population size due to the high reproductive and dispersal rates of Wolves (Mech et al. 1998; Hayes et al. 2003). Forest harvesting can increase human access and change the amount and spatial distribution of habitats for Wolves and their prey. Wolf packs in our study area had a seven-fold difference in the amount of forest harvested within their territories (Kuzyk et al. 2004). The Cutbank pack (n = 7-8) had 36% of the forest in their territory harvested whereas the Lynx Creek (n = 12-18) pack had 7% harvested. The lowest level of forest removal corresponded with the largest pack size of 18 Wolves. In 2001, this pack contained 12 black and 6 gray Wolves and was observed traveling on a road in an open forest cutblock (Kuzyk 2001). This pack size exceeds the largest recorded from nearby studies: 12 Wolves in the Simonette River area (Bjorge and Gunson 1989) and 10 Wolves in northern Jasper National Park (Weaver 1994).

The color phase of a Wolf may influence its detection by humans (Mech et al. 1998) and subsequent mortality. Radiocollared Wolves in this study were predominantly black (61%), similar to those recorded in nearby Jasper National Park (53% black) (Dekker 1986). It is noteworthy that black Wolves may change to a lighter color possibly due to aging or physiological stress (Gipson et al. 2002). Black Wolves may be more easily detected by hunters, especially during winter and on fragmented landscapes. The two Wolves shot during our study were black, and of the seven total mortalities (2 shot, 5 natural or unknown), five Wolves were black (71%).

Lone and small groups of Wolves are also an important component of this population. During the two years of our monitoring, several Wolves dispersed from their natal territories, as individuals or in small groups (<3 Wolves), consistent with other research (Gese and Mech 1991). These lone Wolves, or small groups, could represent 10-30% of the Wolf population (Fuller 1989; Mech et al. 1998) and may be an important factor when assessing predation risk to Caribou. Such Wolves would be travelling great distances to establish new territories (Mech 1970), and may use human trails as travel routes

(Kuzyk and Kuzyk 2002), thereby increasing their chances of encountering Caribou. In addition, pairs of Wolves may have proportionately higher kill rates than larger packs (Hayes et al. 2000). Further, if Wolf packs generally avoid Caribou habitats due to a lack of Moose (James et al. 2004), dispersing Wolves may select these habitats to avoid being killed by resident pack Wolves defending their territories, a primary cause of natural Wolf mortality (Mech 1994). Conducting research on single or small groups of Wolves would be logistically difficult but resulting information could lead to important insights into Caribou predation risk from Wolves.

Documenting current pack size and prey relations of Wolves in our study area is an important step in understanding the potential implications of landscape change and resultant alteration of predator/prey systems for Caribou in the area. However, as pack size could theoretically remain constant while overall numbers increase, determining Wolf density is necessary. In combination with additional information on kill rates and prey availability, this would permit evaluation of the numerical and functional responses of Wolves in this system to landscape alteration, and provide a foundation for examining alternative management strategies aimed at long-term Caribou conservation.

Acknowledgments

Funding for this research was provided by the West-Central Alberta Caribou Standing Committee; the Alberta Sport, Recreation, Parks and Wildlife Foundation; a University of Alberta Challenge Grant in Biodiversity (supported by the Alberta Conservation Association); and the Foothill Model Forest. We acknowledge the safe piloting conducted by C. Wilson from Bighorn Helicopters and D. Dennison from Coyote Air during Wolf captures and monitoring. S. Shirkoff and K. Lisgo provided logistical and data management support. The spatial data on the figure is published with permission of Alberta Sustainable Resource Development, Natural Resource Canada and the Spatial Data Warehouse. Thanks to K. Smith for helpful comments on earlier drafts of this paper.

Oldham, Michael J., Clive E. Goodwin, and Sean Blaney. 2006. Bur Buttercup, *Ranunculus testiculatus*, new to eastern Canada. Canadian Field-Naturalist 120(3): 319–322.

Bur Buttercup (*Ranunculus testiculatus*) is newly reported for eastern Canada based on two collections from campgrounds in southern Ontario. This vernal, annual, Eurasian weed is widespread in western North America and is expanding its range in the east; it should be expected elsewhere in eastern Canada. Bur Buttercup is known to be toxic to livestock.

Key Words: Bur Buttercup, *Ranunculus testiculatus*, Ranunculaceae, first records, weed, range expansion, campground, Ontario, eastern Canada.

On 17 April 2004, Blaney found an unusual buttercup growing on a campsite in Long Point Provincial Park, on the north shore of Lake Erie, Norfolk County, Ontario (42.58°North, 80.41°West). A few days later on 22 April 2004, Goodwin found the same species growing in a municipal campground in Cobourg, on the north shore of Lake Ontario, Northumberland County, Ontario (43.96°North, 78.16°West). This distinctive plant, called Bur Buttercup (*Ranunculus testiculatus* Crantz), has not previously been reported from Ontario (Morton and Venn 1990; Newmaster et al. 1998) or eastern Canada (Scoggan 1978; Gleason and Cronquist 1991; Whittemore 1997; Kartesz 1999).

Ranunculus testiculatus is a small scapose, somewhat tomentose, annual in the buttercup family (Ranunculaceae) which flowers early in the season. The leaves are entirely basal and are 1.5 to 4 cm long, ternate to biternate, with narrow linear divisions. The several leafless peduncles are 2 to 8 cm tall, and each bears a single, inconspicuous pale yellow flower (Figure 1). The fruiting heads are bur-like when dry and mature, giving the plant its common name, Bur Buttercup. Superficially the plant is very different in appearance from other buttercups and is often placed in a separate genus as *Ceratocephalus testiculatus* (Crantz) Roth by some authors (e.g., Cody 1988; Cusick 1989) or *Ceratocephala testiculata* (e.g., Tutin et al. 1993; Mitchell and Tucker 1997; Kartesz 1999). However, most recent North American floras now include it within *Ranunculus* (e.g., Gleason and Cronquist 1991; Whittemore 1997). A related species, *R. falcatus* L., has been reported from North America, but all reports are apparently based on misidentified material of *R. testiculatus* (Whittemore 1997). Common names used for *R. testiculatus* in North America include Bur Buttercup or Burbuttercup (e.g., Barkworth 1982; Pohl 1984; Cusick 1989; Gleason and Cronquist 1991; Swink and Wilhelm 1994), Hornseed Buttercup (e.g., Cody 1988; Douglas et al. 1999), Sage Buttercup (e.g., Mitchell and Tucker 1997), and Curve-seed-butterwort (e.g., Kartesz 1999).

The first North American report of *Ranunculus testiculatus* was from Utah in 1932, followed by discoveries in other western states soon after: Oregon in 1938, Washington in 1940, and Colorado in 1948 (Barkworth 1982). It continues to spread in western North America (Hitchcock and Cronquist 1973; Taylor 1983; Weber 1990; Whittemore 1997). In Canada, Bur Buttercup has been known from southern British Columbia for some time (Boivin 1966; Scoggan 1978), where it is infrequent in south-central and south-eastern parts of the province in dry disturbed clearings and sagebrush slopes in the steppe zone (Douglas et al. 1999). Cody (1988) reported the species new to Saskatchewan based on a collection from Assiniboia in 1987. Cody (1988) also mapped the Canadian distribution of *R. testiculatus*.

Cusick (1989) was the first to report Bur Buttercup in eastern North America, based on a 1977 collection from South Bass Island in western Lake Erie, and predicted it would be found elsewhere in the Great Lakes region. In New York State it was first collected in 1990 from the parking lot of a campground near Harriman in Orange County by D. J. DeLaubenfels (specimen in the New York State Museum, NYS A18183, personal communication C. Sheviak and T. Weldy). The first Chicago area collection was made in 1991 and with concerted searching it was found in 12 additional Chicago region counties in 1992 and 1993 (Swink and Wilhelm 1994). Other recent new state records are from Nebraska in 1970 (Macgrath and Weedon 1974), Iowa in 1984 (Pohl 1984), and Missouri in 1987 (Ladd and Schuette 1990). Bur Buttercup is considered a significant toxic weed of grazing lands in the western United States and has been responsible for the death of sheep (Olsen et al. 1982, 1983).

Several authors have noted the affinity of this species for campgrounds, particularly in eastern North Amer-

FIGURE 1. Bur Buttercup (*Ranunculus testiculatus*) plants. Long Point Provincial Park, Ontario, 6 May 2004. Photograph by Michael Oldham.

ica, for example the first reports from Iowa, Missouri, New York, Ohio, and the Chicago Region are all from campgrounds (Pohl 1984; Cusick 1989; Ladd and Schuette 1990; Swink and Wilhelm 1994; C. Sheviak personal communication). It seems likely that this species is dispersed by camping vehicles and associated equipment. The bur-like fruiting heads of the buttercup may readily attach to blankets and tents, and are thus carried to campsites that appear to provide ideal disturbed conditions. Other vernal, ephemeral Eurasian weedy species have found a niche in campgrounds and are presumed to have a similar dispersal mechanism, such as *Aira caryophyllea* (Silvery Hairgrass), *Aira praecox* (Early Hairgrass), *Apera interrupta* (Interrupted Windgrass), *Cerastium pumilum* (Curtis' Mouse-ear Chickweed), *Cerastium semidecandrum* (Small Mouse-ear Chickweed), *Erophila verna* (Spring Whitlow-grass), *Myosotis stricta* (Blue Scorpion-grass), *Poa bulbosa* (Bulbous Bluegrass), and *Veronica verna* (Spring Speedwell) (Crins et al. 1987; Oldham et al. 1995; Goltz 1996; Oldham and Zinck 1997). Both Ontario records are from campgrounds, a municipal campground in Cobourg, Northumberland County, and a provincial park campground at Long Point, Norfolk County. At both Ontario locations Bur Buttercup is well established but quite local. At Long Point Provincial Park at least 500 plants occur, but they were found on only a single campsite, possibly suggesting a relatively recent introduction. In addition, the Long Point peninsula has been relatively well botanized in the past (Reznicek and Catling 1989). At Cobourg, Bur Buttercup grew in open, disturbed ground on at least four campsites with *Erophila verna* and *Taraxacum officinale* (Common Dandelion), while at Long Point it was found in sandy soil beneath planted Scots Pine (*Pinus sylvestris*) with *Cerastium semidecandrum*, *Stellaria pallida* (Lesser Chickweed), *Poa annua* (Annual Bluegrass), *Myosotis stricta*, and *Taraxacum officinale* (Figure 2).

Collection data for the Ontario records are as follows:

ONTARIO, Norfolk County, Long Point Provincial Park, 42.58°North, 80.41°West, 6 May 2004, *M. J. Oldham 29983* (DAO, MICH, NHIC, TRTE, UWO).

Northumberland County, Cobourg Municipal Campground, 43.96°North, -78.16°West, 9 May 2004, *M. J. Oldham 29996* (DAO, MICH, NHIC, TRTE).

Acknowledgments

Troy Weldy and Charles Sheviak provided information on Bur Buttercup in New York state. The comments of two anonymous reviewers were helpful in improving the manuscript.

Noel, Lynn E., Matthew K. Butcher, Matthew A. Cronin, and Bill Streever. 2006. Assessment of effects of an oil pipeline on Caribou, *Rangifer tarandus granti*, use of riparian habitats in arctic Alaska, 2001–2003. Canadian Field-Naturalist 120(3): 325–330.

Elevated oil field pipelines may alter Caribou (*Rangifer tarandus granti*) movements and delay or prevent access to insect relief habitat. In an attempt to determine if the 40-km elevated Badami pipeline in northern Alaska changed Caribou use of riparian habitats at the three river crossings where the pipeline is buried, we quantified Caribou habitat use at all three crossings using time-lapse video cameras and aerial distribution surveys over three summers. We compared habitat use, behavior and duration of observations among pipeline and non-pipeline sites. We used a block experimental design with cameras at four sites at the three river crossings to evaluate differences in numbers of Caribou per day at pipeline and non-pipeline sites. At each crossing, four cameras were positioned, with one pair of cameras next to the pipeline (pipeline sites) and one pair of cameras 1.8-3.2 km upstream from the pipeline (non-pipeline sites); where cameras monitored the river bank and channel (river habitat) and the tundra within about 200 m of the river (tundra habitat). Peak numbers of Caribou per day occurred during early July 2003 and mid-July 2001 and 2002. Large numbers of Caribou recorded north of the pipeline during aerial surveys did not usually correspond with increased number per day recorded by cameras suggesting Caribou probably also crossed the pipeline outside of the riparian areas. We assessed local changes in riparian habitat use by comparing the numbers of Caribou per day in river and tundra habitats at pipeline and non-pipeline sites and found no difference. We assessed regional changes in riparian habitat use by comparing numbers of Caribou per day at pipeline sites and at non-pipeline sites and found no difference. Caribou groups spent an average of 1 minute longer at tundra pipeline sites and groups spent 30 seconds longer feeding and trotting at pipeline sites, but these differences were not significant.

Key Words: Caribou, *Rangifer tarandus granti*, aerial survey, insects, Badami pipeline riparian habitat, summer, time-lapse video, Alaska.

In northern Alaska, Caribou (*Rangifer tarandus granti*) regularly use insect relief habitats during the summer (Cameron and Whitten 1979; Murphy and Curatolo 1987; Walsh et al. 1992; Pollard et al. 1996a, b; Young and McCabe 1998). This frequently involves north-south movements from inland feeding habitats to coastal insect relief habitats (Cameron and Whitten 1979; Pollard et al. 1996b). Oil transport pipelines traverse open tundra and riparian corridors, often in an east-west direction, so there is the potential for obstruction of movements to and from insect relief habitats (National Research Council 2003). Previous work has shown that pipelines associated with roads can have an impact Caribou movements (Murphy and Lawhead 2000); however, impacts from pipelines not associated with roads and elevated ≥ 1.5 m above the tundra, a height designed as a mitigation to allow Caribou passage (Cronin et al. 1994*), have not been documented.

One such pipeline on Alaska's north slope runs 40 km from the Badami oil production site to the oil fields at Prudhoe Bay. Most of the Badami pipeline is elevated about 1.5 m above the tundra, but it is buried underneath the three rivers it crosses (Figure 1 and 2). Caribou are common in this area during the summer, and aerial surveys document animals on the north and south sides of the pipeline, indicating that they cross the pipeline (Jensen and Noel 2002*; Jensen et al. 2003*; Noel and Cunningham 2003*). However, the elevated sections of this pipeline could alter Caribou movement and delay access to coastal habitats (National Research Council 2003). If this occurs, Caribou should be more likely to cross the pipeline in the riparian zones (including the river and adjacent tundra) where the pipeline is buried. We recorded Caribou by using time-lapse video and aerial distribution surveys over three years to assess whether Caribou use of riparian habitats was influenced by the pipeline.

Methods

Study Area

A 40-km elevated pipeline extends from the Badami facility (70°9'2.71"N, 147°1'25.93"W) across undeveloped terrain to the Endicott pipeline near the Prudhoe Bay oil field (70°15'18.25"N, 148°1'32.75"W, Figure

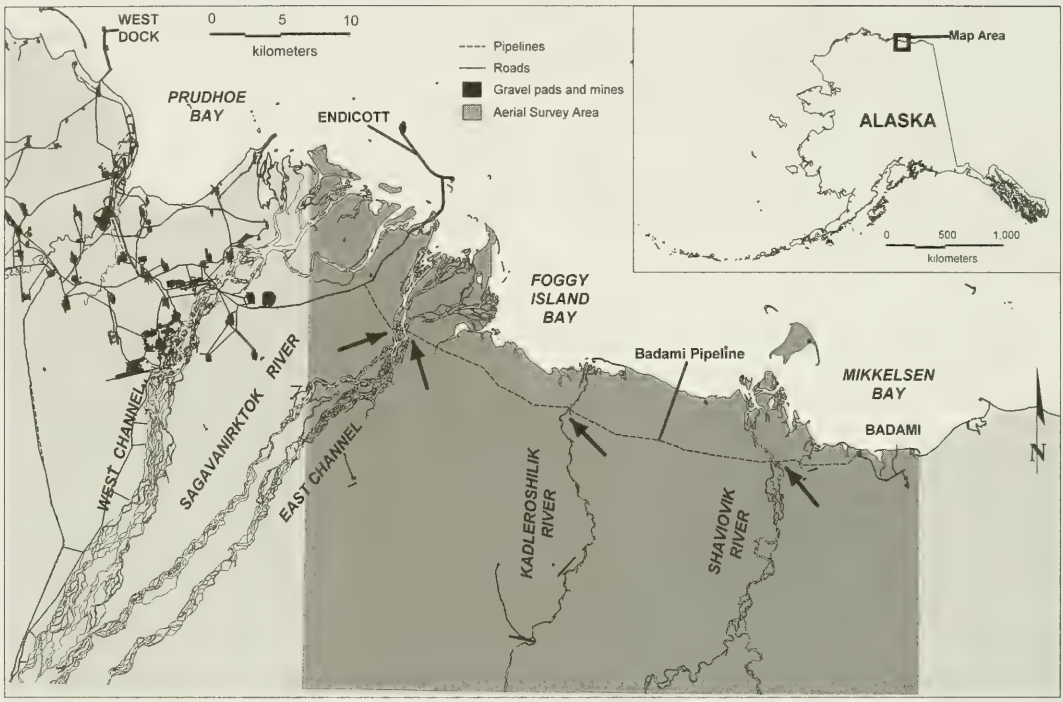

FIGURE 1. Study area, North Slope, Alaska. Arrows indicate study sites.

1). The Badami pipeline is elevated ≥ 1.5 m above the tundra surface for > 99% of its length. This pipeline is buried beneath the East Channel of the Sagavanirktok, Shaviovik, and Kadleroshilik rivers. At the Sagavanirktok and Shaviovik rivers, the pipeline is buried for about 1000 m; at the Kadleroshilik River the pipeline is buried for about 400 m. The Sagavanirktok River crossing is split into two channels by a large vegetated river bar; requiring two sites to be monitored. The tundra between these river channels is a gently rolling thaw-lake plain landscape with elevation rises of 6 to 8 m (Walker and Acevedo 1987).

Time-Lapse Videography

We used time-lapse video camera assemblies to monitor Caribou movements between 19 June and 26 August in 2001, 2002, and 2003. Each camera assembly consisted of a GYYR™ TLC1800-DC time-lapse videocassette recorder and a Panasonic™ WV-CL 322 color CCTV digital camera equipped with a Computar™ APC auto-iris 8.5 mm semi wide-angle lens (Pollard and Noel 1994*; Noel et al. 1998). Each assembly was powered by four 12-volt, 80-amp sealed lead acid batteries, charged by four Solarex™ SX-56 photovoltaic panels. The video recorder, camera, and batteries were housed in insulated aluminum casings to protect them from weather and animals. The time-lapse video recorders were set to record at 3–4 second intervals. Markers were placed 100 m from each camera to assist in determining visibility and to standardize the area sampled. Cameras had a 72° view angle resulting in a 7260-m^2 field of view out to 100 m (i.e., the sampling area). Videotapes were changed at 10–13 day intervals.

The cameras were arranged as follows at four river crossings (Figure 1): (1) the east side of the buried East Channel Sagavanirktok crossing (E Sag), (2) the west side of the buried East Channel Sagavanirktok crossing (W Sag), (3) the east side of the Shaviovik River crossing (Shav), and (4) the east side of the Kadleroshilik River crossing (Kad). At each crossing, four cameras were positioned, with one pair of cameras next to the pipeline (pipeline sites) and one pair of cameras 1.8-3.2 km upstream from the pipeline (non-pipeline sites) (Figure 2). One of each pair of cameras monitored the river bank and channel (river habitat), while the other monitored the tundra within about 200 m of the river (tundra habitat).

Non-pipeline sites with river channel width and configuration and tundra habitats similar to those of the corresponding pipeline sites were selected to reduce variability. This arrangement allowed us to collect Caribou data in four settings at each river crossing (Figure 2): (1) along the pipeline corridor where the pipeline was buried under the river (buried pipeline site/river habitat), (2) along the pipeline corridor where the pipeline was elevated above the tundra (elevated pipeline site/tundra habitat), (3) 1.8–3.2 km upstream from the

pipeline at the river's edge (non-pipeline site/river habitat), and (4) upstream from the pipeline on the tundra (non-pipeline site/tundra habitat).

Videotapes were viewed and the number of Caribou groups seen each day by each of the cameras was recorded. Caribou groups were defined by lapses of 15-30 seconds of tape with no Caribou observations. For each group observed within 100 m of the camera, data for the number of individuals, sex/age category, predominant behavior, and direction of movement were recorded. Caribou group behaviors included: feeding, resting (laying), standing, walking, trotting, running, and swimming.

Aerial Surveys

Eleven systematic aerial strip-transect surveys were completed from a Cessna 206 fixed-wing aircraft (Caughley 1977) to document the number of Caribou within a 1043 km^2 area surrounding the Badami pipeline between 25 June and 1 August 2001-2003 (Figure 1) (Jensen and Noel 2002*; Jensen et al. 2003*; Noel and Cunningham 2003*). Transect centerlines were spaced at 1.6-km intervals, oriented north-south, and centered on township and section lines from 1 : 63360 scale U.S. Geological Survey (USGS) topographic maps. Transects were flown at 90 m altitude and 130–180 km/h. Two observers, each searching an 800-m wide area on their side of the transect centerline, provided 100% coverage of the survey area. Aircraft wing struts were marked to enable visual control of transect strip width and estimation of distance between Caribou groups and the survey aircraft (Pennycuick and Western 1972). Global positioning system (GPS) receivers were used for navigating the aircraft along transects and for estimating the location of the aircraft when animals were observed. The locations of animals were recorded using a GPS receiver linked to a notebook computer. For each sighting, species, group size, group composition, and perpendicular distance from the aircraft were recorded. Coordinates of animal sightings were later calculated using the visual estimates of distance from the aircraft to offset the GPS aircraft positions. Geographic Information System (GIS) software was used to complete geographic summaries.

Weather Data

An automated weather station was established near the East Channel Sagavanirktok River. Temperature (T100 probe with radiation shield) and wind (Gill 3-cup anemometer, Gill low threshold vane) sensors transmitted readings at 5-min intervals to a data recorder which averaged and stored values as mean hourly wind speed and mean hourly air temperature data (Dryden R2® data logger, Anchorage, Alaska).

Data Analysis

The cameras were arranged to create a complete block experimental design (Steel and Torrie 1980). Each river location (E Sag, W Sag, Kad, or Shav) was a complete block containing all four settings: buried pipeline site/river habitat, elevated pipeline site/tundra habitat, non-pipeline site/river habitat, and non-pipeline site/tundra habitat, resulting in two cameras at the pipeline site and two cameras at the non-pipeline site (Figure 2). The potential for the pipeline to change Caribou habitat use was assessed by comparing mean numbers of Caribou per day (averaged for each year) among the four settings, and by evaluating the direction, duration and behavior of Caribou observed by the time-lapse cameras. We summarize the aerial survey data to compare the numbers of Caribou recorded using time-lapse cameras to the numbers of Caribou within the survey area, north of the pipeline and within riparian habitats. Riparian habitats were defined as a 200 m area surrounding the Sagavanirktok, Kadleroshilik, and Shaviovik rivers (Figure 1). Observation duration, direction of movement, behavior, temperature, and

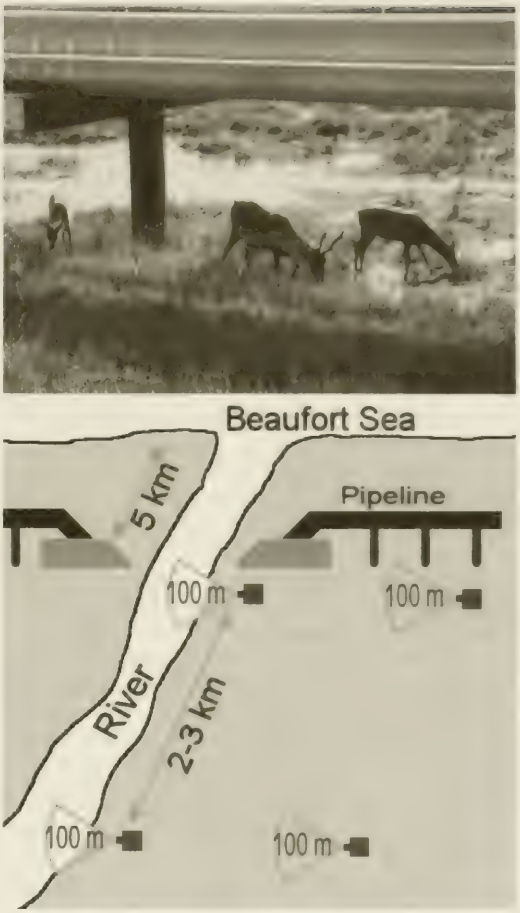

FIGURE 2. Top: An elevated pipeline on Alaska's North Slope. Bottom: Schematic showing the positions of four cameras relative to a river and the Badami Pipeline. As shown, the pipeline is buried at river crossings. (Drawing by Daniel King not to scale.)

wind speed were compared among habitats and with and without the pipeline using a general linear model and analysis of variance (ANOVA).

The block design allowed for the evaluation of local (within the riparian zone) and regional changes in Caribou use of riparian habitats. At a local scale, if Caribou changed habitat use due to the elevated pipeline within the riparian zone (i.e., within 200 m of the river bank), we would expect more Caribou to use river habitat at the pipeline sites compared to river habitat at the non-pipeline sites, as Caribou would avoid the elevated portion of the pipeline by crossing at the river where the pipeline was buried. At a regional scale, if Caribou moved toward the riparian corridors along the pipeline corridor, we would expect to see more Caribou at the pipeline sites (both river and tundra habitats) than at the comparable non-pipeline sites (both river and tundra habitats), as blockage of direct north-south movements by the elevated pipeline would lead to east-west Caribou movements along its length.

We used complete block ANOVA to assess local and regional changes in Caribou use of riparian habitats. Because of the lack of independence between counts of Caribou on consecutive days, we averaged the number of Caribou per day across each year, and used this mean as the response variable, giving an overall sample size of n=47. The ANOVA model was:

Caribou per day = Constant + Location + Year + Pipeline + Habitat + (Pipeline × Habitat),

where:

Constant = overall mean Caribou per day

Location = a block for each river crossing (W Sag, E Sag, Kad, or Shav),

Year = each year of the study (2001, 2002, and 2003)

Pipeline = pipeline site or non-pipeline site, and

Habitat = river or tundra.

All statistical analyses were conducted with SYSTAT® Version 10.2 (SYSTAT® Software Inc., Richmond, California).

Results and Discussion

Peak numbers of Caribou per day were recorded during early July in 2003 and mid July in 2001 and 2002 (Figure 3). Peaks in mean daily temperature coincided with increased numbers of Caribou per day recorded by cameras during late June and early July, but trends were not consistent. During the 11 aerial surveys between 25 June and 1 August 2001–2003, 36% of the Caribou were distributed north of the pipeline within 13% of survey area and 17% of the Caribou were within riparian habitats representing 9% of survey area (Table 1). Generally, when few Caribou were recorded within the survey area, no Caribou were recorded by the time-lapse cameras (Table 1, Figure 3).

The sex-age distribution of Caribou occuring within the survey area was dominated by adult cows (61%–70%) based on the aerial survey data (Table 1). These sex-age distributions are estimates and likely underrepresent calves based on the results of fall composition surveys for this herd of 28% bulls, 42% cows and 30% calves (Lenart 2003*). Sex-age distributions based on time-lapsed video were more similar to fall composition results (Lenart 2003*), but nearly half of the individuals were unclassified (Table 1).

Mean annual Caribou per day by camera ranged from 0.3–20.4 across habitats, pipeline configurations, river locations, and years (Table 2). Least squares means from the ANOVA show that Caribou were more abundant in tundra habitats (mean = 8.9 Caribou per day) than in river habitats (mean = 3.3 Caribou per day) (Table 3). This difference between habitats was the only significant factor ($P = 0.02$, Table 4).

If local habitat use changed because of the presence of the elevated pipeline, more Caribou would have been seen in river habitat than in tundra habitat at the pipeline sites. This local effect was reflected in the ANOVA Habitat × Pipeline interaction term, which was not significant ($P = 0.64$, Table 4). The difference between mean Caribou per day in tundra and river habitats (7.6 and 3.2 Caribou per day, respectively) was smaller for pipeline sites than for non-pipeline sites (10.4 and 3.5 Caribou per day, respectively).

Because we detected no effect on numbers of Caribou per day, we evaluated the duration that Caribou were recorded at pipeline and non-pipeline sites on the tundra (Table 5). Blockage of northward or southward movements across the pipeline corridor could result in delays at pipeline sites, which would be reflected in duration and behavior at these sites. Groups moving north appeared to spend an average of one minute longer at pipeline sites in tundra habitats, while groups moving south spent about two minutes longer at non-pipeline sites (Table 5). A general linear model was used to test whether the presence of the pipeline affected observation duration for Caribou moving northward potentially seeking refuge from insects. Neither the presence of the pipeline nor the explanatory variables habitat (river versus tundra), temperature, and wind speed (atmospheric conditions may have an effect on the severity of insect harrassment) had statistically significant ($P = 0.05$) effects on the observation duration for Caribou moving northward. Duration of group behaviors indicated that Caribou spent about 30 seconds longer feeding and trotting on the tundra at pipeline sites than non-pipeline sites (Table 6). Separate ANOVAs were applied to the duration of feeding, trotting, and walking activities in different habitats (river and tundra) and in the presence or absence of the pipeline. For trotting and walking, neither habitat nor pipeline or their interaction were significant explanatory variables ($P > 0.2$). For feeding Caribou, the duration within tundra (mean = 00:01:09) was significantly longer than within river (mean = 00:06:35, $P = 0.002$).

If the pipeline caused regional changes in Caribou riparian habitat use, we would expect to see more Caribou at the pipeline sites than at the non-pipeline sites. However, the difference between mean Caribou per day at the pipeline and non-pipeline sites (5.4 and 6.8 Caribou per day, respectively, Table 3) was not signifi-

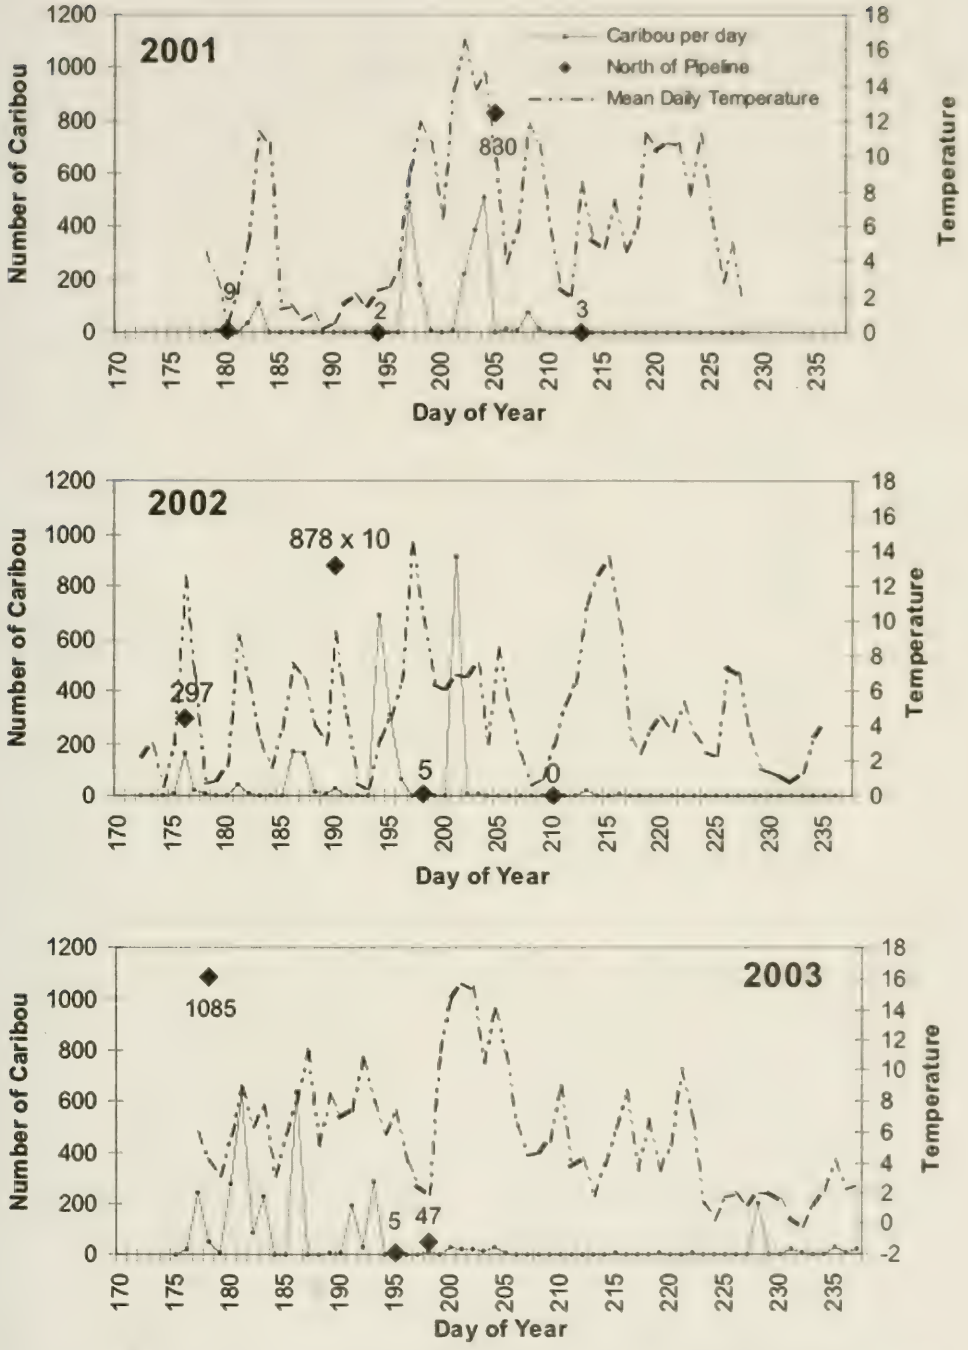

FIGURE 3. Comparison of numbers of Caribou recorded per day for all time-lapse cameras, numbers of Caribou recorded in riparian habitats north of the Badami pipeline corridor during aerial surveys (Figure 1), and mean daily temperature (°C), 19 June (day 170) 26 August (day 238) 2001–2003, North Slope, Alaska.

cant ($P = 0.57$, Table 4). Peaks in the number of Caribou north of the pipeline in 2002 and 2003 did not coincide with large numbers of Caribou recorded at cameras, suggesting that Caribou crossed the pipeline outside of riparian areas (Figure 3).

The results of this study support the conclusion that pipelines elevated ≥1.5 m above the tundra did not cause changes in Caribou riparian habitat use at buried river crossings or delay north-south movements to and from coastal insect relief habitats (Cronin et al. 1994*, Murphy and Lawhead 2000).

Jung, Thomas S., Amy M. Runck, David W. Nagorsen, Brian G. Slough, and Todd Powell. 2006. First records of the Southern Red-backed Vole, *Myodes gapperi*, in the Yukon. Canadian Field-Naturalist 120(3): 331–334.

Twenty Southern Red-backed Voles, *Myodes gapperi*, were collected in July 2004 in the LaBiche River valley of southeastern Yukon. Specimens were identified using morphological characteristics and analysis of cytochrome *b* gene sequences. These are the first records of this species in the Yukon. No Northern Red-backed Voles, *M. rutilus*, were collected and it is not known whether the two species are sympatric or parapatric in the Yukon. Further survey work is needed in southeastern Yukon to better delineate the extent of the northwestern range of this species and the extent, if any, of introgression with *M. rutilus*.

Key Words: Southern Red-backed Vole, *Myodes gapperi*, distribution, Yukon.

The Southern Red-backed Vole (*Myodes* [formerly *Clethrionomys* see Musser et al. 2005] *gapperi*) is broadly distributed across the boreal, montane, Pacific coastal, and other conifer-dominated forests of North America (Banfield 1974; Merritt 1981; Batzli 1999). Youngman (1975) did not report *M. gapperi* from the Yukon, in part, because he was of the opinion that *M. gapperi* and the Northern Red-backed Vole (*M. rutilus*) were conspecific. Cook et al. (2004), however, provided molecular data that reinforced the separate status of *M. gapperi* and *M. rutilus*. North American species of *Myodes*, including *M. gapperi* and *M. rutilus*, are cryptic and field identification is highly problematic where congeners come into contact (Merritt 1981; McPhee 1984; Runck 2001, Nagorsen 2002, 2005; Cook et al. 2004). Therefore, we considered that *M. gapperi* may have been overlooked in the Yukon due to the difficulty in distinguishing specimens from *M. rutilus* in the field, and a general paucity of mammalian diversity surveys in most of the Yukon. Based on the distribution of *M. gapperi* in adjacent northeastern British Columbia and southwestern Northwest Territories (Banfield 1974; Nagorsen 2005) we suspected the greatest likelihood of finding the species in the Yukon was in the Liard River Watershed. In summer 2004, we undertook a brief field survey of mammalian diversity in the boreal forest of southeastern Yukon, partially with an aim to procuring specimens of *M. gapperi*. Here, we provide the first records of the Southern Red-backed Vole in the Yukon.

Methods

On 28 July – 2 August 2004, we used pitfall and snap traps to collect shrews and rodents in the LaBiche River Valley (60.126°N, 124.064°W) of southeastern Yukon. Seven habitats were sampled: wet meadows and shrub thickets adjacent to Beaver (*Castor canadensis*) ponds; xeric grassy meadows; riparian old-growth White Spruce (*Picea glauca*) forest; lowland Black Spruce (*Picea mariana*) forest; subalpine old-growth Spruce-fir (*Abies lasiocarpa*) forest; second-growth mixedwood forest; and regenerating clearcut forest. All habitats were sampled with snap traps. We established 14 variable length traplines (ca. 100 m – 250 m) in each of the seven habitat types. Trap stations were set 10 m apart on the traplines. One Museum Special snap trap and one Victor snap trap (Woodstream, Lititz, Pennsylvannia) were set at each trapping station. Traps were baited with oats and peanut butter, run for 2-3 days and checked each morning. In addition to the snap traps, we established three traplines of metal conical pitfall traps in the wet meadow habitats, primarly to capture soricids. Pitfall traps were 25 cm in height and 15 cm in diameter at the top. Pitfall traps were also arranged in traplines with one trapline in each of the wet meadows sampled. Traps were spaced about 10 m apart, with 15 or 20 traps per trapline, and installed flush with the ground surface. Pitfall traps were not baited and they were left open for 3-5 days. Each morning we checked the traps and processed the captures.

Captures were tentatively identified to species, measured, aged, weighed, sexed, and examined for reproductive condition. Whole carcasses were frozen on site. Species were tentatively identified in the field using morphological, pelage, and dental characteristics, following Nagorsen (2002) and van Zyll de Jong (1983). Because of the difficulty in distinguishing *M. rutilus* from *M. gapperi* in the field, we undertook subsequent laboratory investigations at Idaho State University (Pocatello, Idaho) to confirm our field identifications. All skulls were examined for fusion of the post-palatal bridge (Merritt 1981; Nagorsen 2002) and the first 600 base pairs (bp) of mitochondrial cytochrome *b* gene were examined to confirm species identification. Restriction enzyme screening and sequencing of cytochrome *b* followed established protocols for *Myodes* (Runck and Cook 2005). All individuals underwent restriction enzyme digestion using the restriction enzyme ALU I to determine the presence of the restriction site AGCT which is found in the 600 bp fragment of the cytochrome *b* gene in *M. rutilus* but not *M. gapperi* (Runck 2001). Five random individuals were sequenced for the first 600 bp of the cytochrome *b* gene and were used in a phylogenetic reconstruction using published sequences of *Myodes* (Cook et al. 2004; Runck and Cook 2005), representing *M. gapperi* ($n = 10$), *M. rutilus* ($n = 2$), *M. californicus* ($n = 1$), *M. glareolus* ($n = 1$), and *M. rufocanus* ($n = 1$). Sequences for specimens not collected in LaBiche (Figure 1) were taken from GenBank. Phylogeographic reconstruction was conducted using neighbor-joining framework in PAUP b10 (Swofford 2002) using the Tamura and Nei (1993) model of sequence evolution as determined through Modeltest (Posada and Crandall 2000).

Results and Discussion

We captured 20 *Myodes* during sampling. Field identification, based on morphological (tail and pelage) characteristics, suggested that all captures were of *M. gapperi*. Further, 15 of the 20 specimens had complete post-palatal bridges, which is a primary diagnostic characteristic of *M. gapperi* (Merritt 1981; Nagorsen 2002). Two specimens had incomplete post-palatal bridges and the bridges of a further three were broken by the traps and not usable as a diagnostic character. Genetic analyses using restriction enzyme screening and sequencing of cytochrome *b* gene confirmed that all 20 specimens of *Myodes* collected in the LaBiche River Valley were *M. gapperi* (Figure 1).

The Southern Red-backed Vole is now added to the list of mammals in the Yukon. This is the first additional rodent found in the Yukon since Youngman (1975). These 20 specimens were deposited at the Museum of Southwestern Biology at the University of New Mexico (Albuquerque, New Mexico).

Capture rates were 0.28 per 100 trap nights (TN) and 1.32 per 100 TN in pitfall and snap traps, respectively. Captures of *M. gapperi* represented the range of sex and age classes (5 adult females, 7 adult males, 5 juvenile females, and 3 juvenile males), confirming that a breeding population was present. *M. gapperi* were taken in all of the habitats sampled. Species caught in association with *M. gapperi* in the LaBiche River Valley included: Meadow Voles (*Microtus pennsylvanicus*, $n = 14$), Deer Mice (*Peromyscus maniculatus*, $n = 13$), Meadow Jumping Mice (*Zapus hudsonius*, $n = 10$), Eastern Heather Vole (*Phenacomys ungava*, $n = 1$), Masked Shrew (*Sorex cinereus*, $n = 1$), Pygmy Shrew (*Sorex hoyi*, $n = 1$), and Dusky Shrews (*Sorex monticolus*, $n = 2$).

We do not know the extent of the range of the Southern Red-backed Vole in the Yukon. They have been collected, however, near Fort Liard, Northwest Territories (S. Carrière, unpublished data; Runck and Cook 2005). Specimens from near Watson Lake, Yukon (ca. 270 km W of the present study; $n = 43$), were also analyzed in the lab using skull and genetic characters and they were determined to be *M. rutilus* (T. S. Jung and A. M. Runck, unpublished data), suggesting that *M. gapperi* may not be widely distributed in southern Yukon. Perhaps *M. gapperi* is restricted in the Yukon to the extension of the Boreal Plain ecoregion in the extreme southeast. Further surveys from nearby river valleys, and subsequent DNA analysis, are needed to better document the ranges and contact zone of *M. gapperi* and *M. rutilus* in southeastern Yukon and adjacent British Columbia and Northwest Territories. Our discovery of *M. gapperi* in extreme southeastern Yukon, along with that of the Yukon's only records of Northern Long-eared Bats (*Myotis septentrionalis*; Jung et al. 2005) and other taxa (e.g., some species of neotropical migrant passerines: Eckert et al. 1997), suggests that this ecoregion may be a zoogeographically unique part of the Yukon.

Acknowledgments

The staff of Devon Canada Corporation's LaBiche River Gas Plant kindly went out of their way to accommodate us and provide logistical support. Funding was provided by the Yukon Department of Environment, NatureServe Yukon, and a Northern Research Endowment Grant from the Northern Research Institute, Yukon College, to B. Slough. Thoughtful comments from S. Cannings, and five anonymous reviewers improved the manuscript.

A Conservation Evaluation of Smooth Goosefoot, *Chenopodium subglabrum* (Chenopodiaceae), in Canada

DIANA BIZECKI ROBSON

The Manitoba Museum, 190 Rupert Avenue, Winnipeg, Manitoba R3B 0N2 Canada

Robson, Diana Bizecki. 2006. A conservation evaluation of the Smooth Goosefoot, *Chenopodium subglabrum* (Chenopodiaceae), in Canada. Canadian Field-Naturalist 120(3): 335–341.

Smooth Goosefoot (*Chenopodium subglabrum*) is restricted to North America and reaches its northern distribution limit in Alberta, Saskatchewan and Manitoba. The habitat of *Chenopodium subglabrum* contains some element of active sand. It is commonly found on the stabilizing edges of active dunes as well as dune blowouts, and occasionally on bare or recently disturbed sand plains. *Chenopodium subglabrum* is a sexually reproducing annual species with seeds that may remain in the seed bank for several years, waiting for the conditions it favours for germination. Germination of this species is erratic, possibly in response to moisture, making the overall population trend difficult to determine. The estimated population in Canada is likely between 5000 and 10000 individuals. There has been considerable loss of habitat as dunes become vegetated. The processes of dune stabilization and fire control threaten survival of this species.

Key Words: *Chenopodium subglabrum*, Smooth Goosefoot, distribution, population size, rare, Alberta, Saskatchewan, Manitoba.

Chenopodium subglabrum (S. Wats.) A. Nels., commonly called Smooth Goosefoot, is a rare, shallow-rooted annual plant (Figure 1) found in the prairie provinces of Canada. Prior to 1990 only small numbers of this species had been observed at 20 sites in Canada (Smith and Bradley 1990*). Search efforts from the mid-1990s on resulted in the discovery of new populations in five Sand Hill regions in Saskatchewan and Manitoba. In 2004, the highest number of individuals ever recorded in Canada was observed, suggesting that this species has a strong temporal component to its rarity. The objective of this paper is to document these recent findings and determine their conservation implications.

Habitat

Chenopodium subglabrum populations occur in the Aspen Parkland, Moist Mixed Grassland, and Mixed Grassland Ecoregions of the Prairie Ecozone (Acton et al. 1998). Within this ecological area, *C. subglabrum* is found in Mixed Grasslands with sandy soils. The populations in Saskatchewan and Alberta are isolated from each other as the land in between them is largely cultivated. The Manitoba populations are particularly isolated, being approximately 500 km from the nearest *C. subglabrum* population in Saskatchewan and about 350 km from the nearest population in North Dakota (Schmoller 2002*). This fragmentation is natural since *C. subglabrum* does not generally grow on the silty and clayey soils that occur in between the various sand hills. The populations that occur along the South Saskatchewan River are less isolated than the ones growing in the sand hills to the south since habitat along the river is largely undisturbed.

Chenopodium subglabrum is an early successional habitat specialist growing typically in the stabilizing

1According to Argus and Pryer 1990
2 According to provincial Conservation Data Centres

sand at the edges of active dunes and blowouts, and along eroding, sandy river banks and coulees (Smith and Bradley 1990*; Robson 1997a; Lamont and Gerry 1998*). It is generally found on south- or west-facing actively eroding slopes, at the edge of stabilizing sand and sometimes in dune slacks. Populations tend to occur in discrete units clustered around active dunes and are typically highest in areas of finer and more compacted sand. Given that *C. subglabrum* was found historically along the South Saskatchewan River, it is possible that much of this species' habitat disappeared when Gardiner Dam was built on the South Saskatchewan River in the late 1960s, flooding the sand bars and terraces. Dynamic factors such as grazing, erosion and fire may aid in destabilizing sand, resulting in more habitat for *C. subglabrum* (Robson 1999).

Commonly associated species include the following: Indian Rice-grass (*Achnatherum hymenoides*), Sand Grass (*Calamovilfa longifolia*), Narrow-leaved Goosefoot (*Chenopodium pratericola*), Canada Wild Rye (*Elymus canadensis*), Northern Wheat-grass (*Elymus lanceolatus* ssp. *lanceolatus*), Prairie Sunflower (*Helianthus petiolaris* ssp. *petiolaris*), Hairy Golden-aster (*Heterotheca villosa* var. *villosa*), Skeleton-weed (*Lygodesmia juncea*) and Lance-leaved Psoralea (*Psoralidium lanceolatum*) (Smith and Bradley 1990*; Robson 1997a). Shrub cover often includes: Common Bearberry (*Arctostaphylos uva-ursi*), Hoary Sagebrush (*Artemisia cana* ssp. *cana*), Creeping Juniper (*Juniperus horizontalis*) and Sandbar Willow (*Salix exigua* ssp. *interior*) (Smith and Bradley 1990*; Robson 1997a). *Chenopodium subglabrum* is also associated with six nationally rare and eight provincially rare plants in various locations (Table 1).

Chenopodium subglabrum is an annual plant with bisexual flowers (Clements and Mosyakin 2004). Flowering occurs from June to August and seed production in August and September (Wallis and Wershler 1988). Although no studies on *C. subglabrum* pollination have been performed, other species in this genus are wind- or self-pollinated (Johnson and Ward 1993; Royer and Dickinson, 1999). The distances that *C. subglabrum* pollen travels is unknown. Since the wind-pollinated *C. pratericola* often occurs in the same habitat with *C. subglabrum*, hybridization may be possible, although it has not been observed (Bassett and Crompton 1982).

The fruits and seeds of *C. subglabrum* lack structures that would aid in wind (i.e., hairs) or animal (i.e., burs or fleshy fruits) dispersal although the seeds may ad-

here to wet fur. The seeds likely fall close to the parent plant and may be buried by shifting sand, or travel short distances in the winter over snow crust. This means that the main exchange of genetic material between populations would occur via pollination. Lamont and Gerry (1998*) asserted that dry weather could limit its germination. The dramatic increase in the number of individuals observed at most sites in Saskatchewan in 2004 coupled with the observation that late summer was unusually wet and cool suggests that maximum seed germination occurs under moist conditions. The seeds can likely remain dormant for several years (Robson 1999). This dormancy can last at least eight years; at the Beaver Creek site plants were observed in 1996 and 2004 but not in the years in between. There may be dormant seeds present in stabilized areas that would germinate under appropriate climatic conditions if the area were denuded of its vegetative cover.

No attempts to propagate the species for seed production have been attempted. If seeds were harvested from the wild and grown in a greenhouse the seeds from those plants could be introduced back into the wild. However, given the species' sensitivity to climate conditions, the seeds may not germinate in the wild the following year making assessment of the introduction success difficult to ascertain.

Chenopodium subglabrum is both a halophyte (i.e., salt-loving plant) and a xerophyte (i.e., dry-loving plant) making it a stress-tolerant species (Grime 1979). Plants in the Chenopodiaceae are generally non-mycorrhizal (Mukerji et al. 2000). Since *C. subglabrum* grows in areas of active sand where mycorrhiza are usually not abundant, it is probably normally non-mycorrhizal.

At several sites in Alberta and Saskatchewan there were specimens of *C. subglabrum* that had been grazed. Grazing may have been by cattle or wildlife. Some grazed plants produced side shoots to compensate for stem loss. A report on Ord's Kangaroo Rat (a nationally rare mammal) ecology noted that there were seeds of *C. subglabrum* found in their pouches and food caches so seed predation occurs (Lamont and Gerry 1998*). The growth of several plants observed appeared to be inhibited by an unidentified purplish fungus infecting the leaves.

The Grassland Natural Region is one of the most threatened natural regions in Canada. Over two-thirds of the Mixed Grassland has been lost to cultivation or other development (Wallis 1987). Although some sandy plains have been cultivated, the hilliest areas have not been. The main limiting factors affecting *Chenopodium subglabrum* are its natural narrow preference for unstabilized sites within dune fields and loss of natural habitat through succession. Large areas of once active sand have become stabilized over the last fifty years. The active sand surface of some dunes in the Milk River Sand Dunes of Alberta has been reduced by 50% to 75% over 40 years (Wallis 1987). In the Middle Sand Hills of Alberta, 90% of the sand that was active in 1950 is now stabilized (Wallis 1987). Hugenholtz and Wolfe (2005) estimate that stabilization rates in the Great Sand Hills of Saskatchewan have ranged from 7.2 to 10.5 ha/yr in the northern portion and 1.3-1.4 ha/yr in the southern portion since 1946. Stabilization rates from 1944 to 1996 in the Elbow Sand Hills have ranged from 0.4 to 1.9 ha/yr (Hugenholtz and Wolfe 2005). In the Seward Sand Hills stabilization rates from 1970 to 1991 were estimated to be 1.2 to 3.8 ha/yr (Hugenholtz and Wolfe 2005). The Tunstall Sand Hills stabilization rates from 1969 to 1991 were estimated to be 0.6 to 3.6 ha/yr (Hugenholtz and Wolfe 2005). In Manitoba only one of the six sand hills still has active dunes (Wolfe 2001). The Brandon (Carberry) Sand Hills stabilization rate from 1928 to 1990 has ranged from 1.8 to 17.7 ha/yr (Hugenholtz and Wolfe 2005; Wolfe et al. 2000).

While the exact mechanisms are unclear, a combination of drought conditions and land use appears to be influential in dune stabilization (Hugenholtz and Wolfe 2005; Wolfe et al. 2001, 2002). If current trends continue, rare native plants that now have dangerously low populations could be eliminated entirely. However, Wolfe and Thorpe (2005) speculate that climate change may result in a potential increase in the susceptibility of sand hills to erosion, possibly reversing this stabilization trend.

Exotic invasive weeds are becoming more common in dune areas and have the potential to usurp *C. subglabrum* habitat (Robson 1997a). Exotic plants observed in the same habitats with *C. subglabrum* include: Crested Wheat-grass (*Agropyron cristatum*), Lamb's-quarters (*Chenopodium album*), Leafy Spurge (*Euphorbia esula* var. *esula*), sweet-clover (*Melilotus* spp.) and Russian-thistle (*Salsola tragus*) (Wallis and Wershler 1988; Schmoller 2002*; Robson et al. 2005). Oil and gas exploration and extraction, and to a lesser extent recreation are also potential threats (Wallis 1987; Robson 1997a; Lamont and Gerry 1998*).

Distribution

Chenopodium subglabrum is found in the prairie provinces of Canada, south to Utah and Colorado, west to Washington and Nevada, and east to the Dakotas, Nebraska and Iowa (Figure 2) (Clements and Mosyakin 2004). The populations in Manitoba, Washington, Nevada, Utah, Colorado and Iowa appear to be disjunct from the species' main range (Clements and Mosyakin 2004).

In Alberta there are populations of *C. subglabrum* in five different regions of sand hills: Grassy Lake, Middle, Rolling Hills Lake, Dominion and Pakowki Lake Sand Hills. In Saskatchewan, *C. subglabrum* has been collected in 11 different sand hill regions: Bigstick-Crane Lakes, Birsay, Burstall, Cramersburg, Dundurn, Elbow, Great, Seward, Pelican Lake, Piapot and Tunstall Sand Hills. In southwestern Manitoba *Che-*

nopodium subglabrum populations are found in the Routledge (White and Johnson 1980; Robson et al. 2005) and Brandon (Carberry) Sand Hills.

Due to the annual nature of this species, the population numbers fluctuate widely. Data collected in 2004-2005 supports this hypothesis. At several Saskatchewan locations fewer than 50 individuals were found in the late 1990s but several hundred were observed in 2004. In the Routledge Sand Hills of Manitoba, 19 plants were observed in 2004 but 68 were seen in 2005. Population fluctuations, possibly in response to climate, make it difficult to accurately estimate the number of plants and the vulnerability of populations. In 2004 there were an estimated 8400 plants growing in Canada; in other years only a few hundred to several thousand plants were observed. However, even though plants may not be growing at a site in a given year, seeds are likely present in the seed bank.

The largest populations occur in the Great and Seward Sand Hills of Saskatchewan, and in the Grassy Lake Sand Hills of Alberta. Based on the observed fluctuations in population size and recognition that at any given year there are some *C. subglabrum* seeds dormant in the seed bank, there are likely between 5 000 and 10 000 plants in Canada. The following is an overview of populations in the three provinces of occurrence.

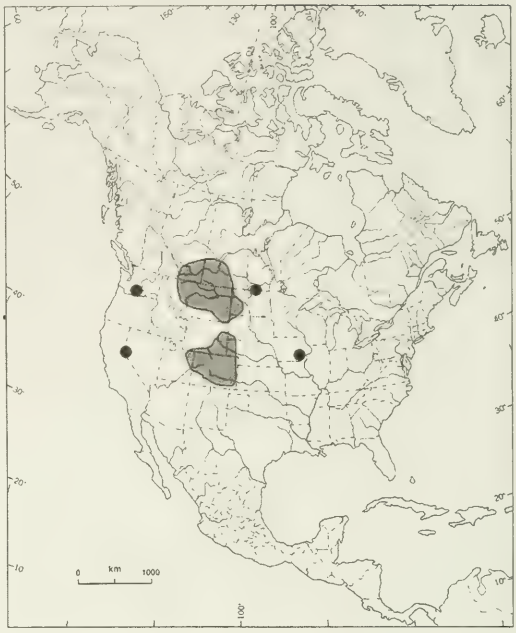

FIGURE 2. Distribution of *Chenopodium subglabrum* in North America.

Alberta

The only Alberta site visited recently (in 2004) was Lost River. Most population research on *C. subglabrum* in Alberta was conducted in the late 1980s (Table 2). Since such a long time has passed since these sites were visited, the dunes may have stabilized further, reducing available habitat.

Saskatchewan

Extensive *C. subglabrum* survey work was done in the mid to late 1990s in the sand hills of Saskatchewan (Robson 1997a; Lamont and Gerry 1998*). Since the first status report was written in 1990 (Smith and Bradley 1990*) new populations have been discovered in the Bigstick-Crane Lakes, Seward, Great and Tunstall Sand Hills (Robson 1997b; Nelson Dynes & Associates 1998*; Lamont and Gerry 1998*) (Table 3). This is balanced somewhat by the apparent loss of five populations where no plants have been observed for at least four decades. The Dundurn, Elbow, Great and Seward Sand Hills locations were visited as recently as 2004.

TABLE 2. Locations and population data for *Chenopodium subglabrum* in Alberta.

Location	Population	Last observation[1]	Population size

Manitoba

Although the species was found near Oak Lake in 1959 it was not observed again until 2004 when it was rediscovered (The Manitoba Museum voucher specimen catalogue # 37136) near Routledge (Robson et al. 2005) (Table 4). The active dunes in the Brandon (Carberry) Sand Hills were also searched for *C. subglabrum* in 2004 but no plants were found. However, in 2005 a small population of nine plants (The Manitoba Museum voucher specimen catalogue # 37859) was located. Two plants were found in the same area in 2006. This is the first record ever for this location and represents a range extension for this species of approximately 100 km east.

Evaluation

Significance

Chenopodium subglabrum plays a role in dune stabilization, being one of the few plants that can colonize active sand. Several related species are important economically, including Quinoa (*C. quinoa*), grown for its seeds, and Good King Henry (*C. bonus-henericus*), grown for its leaves (Everett 1981). The aboriginal peoples of the western United States consumed seeds of *Chenopodium pratericola* and Fremont's Goosefoot (*C. fremontii*) (Smith and Bradley 1990*).

Rarity Status

Chenopodium subglabrum was listed by the Committee on the Status of Endangered Wildlife in Canada in 2006 as being a threatened species in Canada. Legal protection of this species via the *Species at Risk Act, 2003* will likely occur in the next few years. This species is considered rare in all three prairie provinces (Packer and Bradley 1984; Maher et al. 1979; White and Johnson 1980) but is not yet protected by any provincial legislation. This species is not protected by any legislation in the United States.

The NatureServe ranks are Global G3G4 (globally vulnerable to apparently secure), Canada N2 (nationally imperiled), Alberta S1 (provincially critically imperiled), Saskatchewan S2 (provincially imperiled), and Manitoba S1 (provincially critically imperiled). The United States ranks are: Montana S1 (critically imperiled in the state), North Dakota S1 (critically imperiled in the state), Nebraska S3 (vulnerable in the state) and Wyoming S3 (vulnerable in the state) (NatureServe 2005*). In the remainder of the states where it occurs it is has either not been ranked (e.g., Colorado, Idaho, Kansas, Nevada, Oregon, South Dakota, Utah and Washington) or is considered unrankable due to a lack of information (e.g. Michigan) (NatureServe 2005*).

Future Outlook

Chenopodium subglabrum is restricted to sandy habitats in the prairie provinces that are geographically isolated from one another. Due to *C. subglabrum*'s annual nature, it experiences large fluctuations in population size from year to year. Dune stabilization has been occurring at a high rate in all of the sand hill habitats where this species occurs. Increased pressure on these ecosystems from the oil and gas industry, and encroachment of exotic weeds further threaten this species.

Acknowledgments

The Canadian Wildlife Service (Environment Canada), Manitoba Conservation, and the Manitoba Museum Foundation Inc., provided funding for this research. Some of the data in this article were obtained from the original status report on this species prepared by Bonnie Smith and Cheryl Bradley. Thanks are extended to the many scientists, particularly Candace Elchuck and Joyce Gould, who provided information for this report, the landowners for allowing access to their land, and Janis Klapecki, Cary Hamel and Cathy Foster for participating in the field surveys.

Summary Movements and Impact of Individual Striped Skunks, *Mephitis mephitis*, on Duck Nests in Saskatchewan

SERGE LARIVIÈRE[1,3], LYLE R. WALTON[2], and FRANÇOIS MESSIER[3]

Larivière, Serge, Lyle R. Walton, and François Messier. 2006. Summer movements and impact of individual Striped Skunks, *Mephitis mephitis* on duck nests in Saskatchewan. Canadian Field-Naturalist 120(3): 342–346.

Striped Skunks (*Mephitis mephitis*) are important predators of duck eggs in the Canadian prairies. We estimated the impact of individual Striped Skunks on duck nests by intensive observations of foraging movements and depredation of duck nests in southern Saskatchewan, 1993-1994. Nightly, skunk movements were variable (range 0-20 km per night), and did not differ among seasons for females, or between males and females during the parturition/rearing season. Overall, nightly movement of Striped Skunks averaged 7.4 km for females (SD = 5.9 km, n = 20 females) and 6.7 km for males (SD = 3.2 km, n = 5 males). During 1 873 h of radio-tracking, we observed depredation of 10 duck nests by 8 skunks (7 F, 1 M). Using our observed estimate of one depredation for every 187 h, and averaged nightly activity of 8-10 h per night, we estimated that individual skunks find one duck nest every 19-23 nights. Thus, during the 60-day nesting season for ducks (mid-May to mid-July), individual skunks probably find 2-3 duck nests. These observations reinforce the growing evidence that, at normal duck nest densities (<2.5 nests/ha), depredation of eggs by Striped Skunks is opportunistic, and the impact of Striped Skunks on duck nests is a direct function of Striped Skunk abundance.

Key Words: Striped Skunk, *Mephitis mephitis*, duck, movement, nest predation, prairie, predator ecology, Thickwood Hills, Saskatchewan.

Predation on eggs is an important limiting factor for many bird populations (Ricklefs 1969; Martin 1995). In the grasslands of North America, population decline of many species of ground nesting birds is attributed to increased predation on eggs during the breeding season (Böhning-Gaese et al. 1993). Of these birds, ducks (Anatidae) nesting in the prairies of Canada and the United States experience high predation rates on their nests. The primary mammalian predators are Striped Skunks (*Mephitis mephitis*), Red Foxes (*Vulpes vulpes*), Raccoons (*Procyon lotor*), American Badgers (*Taxidea taxus*) and Coyotes (*Canis latrans*). The impact of these predators on duck nest success is well recognized (Klett et al. 1988; Johnson et al. 1989; Pasitschniak-Arts and Messier 1995). However, the contribution of individual animals is poorly understood, yet is critical for management and mitigation of nest predation.

In the parklands of Saskatchewan, the Striped Skunk is an important predator of duck eggs (Pasitschniak-Arts and Messier 1995), yet it depredates duck nests opportunistically (Larivière and Messier 1997a, 1998a). This suggests that the impact of skunks on duck nest success is the result of "chance" encounters with duck nests as skunks forage for other foods such as small mammals and insects (Greenwood et al. 1999). Therefore, the impact of Striped Skunks on duck nests should be a function of (a) habitat selection patterns (do skunks use habitats where ducks nest?), (b) movement rates (the longer the movements by skunks, the greater the chances of discovering a duck nest), and (c) density of skunks (the more skunks, the greater the impact on duck nests). A recent experiment suggested that individual predators were unlikely to key on duck nests at densities <2.5 nests/ha (Larivière and Messier 1998a). Furthermore, partial depredation of duck nests by Striped Skunks commonly occurs (Larivière and Messier 1997a; Ackerman 2002), suggesting that duck eggs may not be a preferred food of skunks or that their importance may be marginal to the overall nutrition of Striped Skunks. An estimate of the impact of individual Striped Skunks on duck nests would help further our understanding of the role that duck eggs play in the foraging ecology of this carnivore. Herein, we estimate the impact of individual Striped Skunks on duck nests by combining intensive radio-tracking and observations of free-ranging Striped Skunks in the Prairie Pothole Region of Saskatchewan, Canada.

Methods

We conducted this study ca. 80 km northwest of Saskatoon in the Thickwood Hills of southcentral Saskatchewan, Canada (52°45'N, 107°08'W). In 1993, the area (ca. 220 km^2) was dominated by farmland and interspersed with many wetlands and stands of trem-

bling aspen (*Populus tremuloides*). Cropland represented 66% of the area, and was primarily used for the production of grain (e.g., wheat, barley, rye, and oats), and oil crops (e.g., canola and flax). Other less common crops included peas, lentils, buckwheat, and canary seed. Woodland and areas managed for nesting waterfowl (mostly dense nesting cover) occupied 11% and 9% of the landscape, respectively. Managed nesting areas consisted mostly of dense nesting cover, hay land, and idle pastures. Fields of dense nesting cover were sown with various tame and wild grasses to create prime habitat for nesting waterfowl. Small or linear cover types such as wetlands, rights-of-way, farmsteads, and miscellaneous habitats represented 8%, 4%, 1%, and 1% of the land available, respectively. Topography was gently rolling, and an extensive network of roads divided the land.

In 1993, Striped Skunks were live-trapped using opaque-sided livetraps (Dura-Poly livetraps, Ram Supplies, Birtle, Manitoba). Captured skunks were anesthetized with halothane and Telazol® (Larivière and Messier 1996a, 1996b), and equipped with motion-sensitive radio-collars (Telonics Inc., Mesa, Arizona, USA). Skunks were handled and released at site of capture.

Radio-collared animals were located and tracked by a single observer on foot from 18:00 to 06:00 h, during the period of greatest activity (Larivière and Messier 1997b). During tracking, a single observer followed the foraging skunk while remaining downwind, and usually within 15-50 m of the animal (Larivière and Messier 1998b). This distance allowed precise location of focal animals every 15 min, and allowed observation of foraging behavior. For short movements (<100 m), distance from previous location was estimated by observer. Locations immediately following an observer-induced defensive posture (n = 198: Larivière and Messier 1996c) were discarded from analyses because of observer disturbance (Larivière and Messier 1998b). At dark, we used night-vision equipment (AN-PVS 5C, Bill's Electronics, Mildmay, Ontario) to continue observations (Larivière and Messier 1998b). Encounters with duck nests typically were easy to detect because of the flushing hen (Larivière and Messier 1997a) or repeated visits to the nest (Larivière and Walton 1998). Depredated nests were investigated immediately following departure of the skunk, and usually reexamined the following day.

For each location, we recorded position of the focal skunk using a Global Positioning System (GPS) unit. We estimated accuracy of our GPS as ± 250 m. To overcome biases associated with the inaccuracy of our GPS on short movements, we only considered the total distance traveled by each skunk during the 12-h tracking period (sum of all 15-min movements). We also only considered complete 12-h blocks for which onset and cessation of activity were known. Missing values (typically caused by delays of the GPS unit to obtain fixes in forested habitats) for ≤2 intervals per night were approximated by the nightly mean of 15-min travel distances. Sessions with >2 missing values were discarded from analyses. Biological seasons for Striped Skunks were identified as pre-parturition (1 April-14 May), parturition/rearing (15 May- 30 June), pre-dispersal (1-31 July), and dispersal (1-31 August).

Each summer (May-August), >50% of radio-collared animals died or dispersed outside the study area (Larivière and Messier 1998c). Thus, the resulting data set was not balanced, and precluded use of repeated-measures analyses, and comparison among seasons. Therefore, we used a one-way analysis of variance to test for effects of season on movements. To avoid biases caused by animals tracked >1 night in a given season, we used the mean distance traveled for each skunk in each season (weighted mean, only one value per animal per season). Because some skunks were tracked during more than one season and they may not have been independent, we used an alpha value of 0.01 to remain conservative and reduce the chance of a Type 1 error.

Results

During 1993 and 1994, we obtained complete movement information for 63 12-h tracking sessions (11 in 1993, and 52 in 1994) on 25 Striped Skunks (5 M, 20 F). Because no skunks were radio-tracked during both years, we pooled data from 1993 and 1994 for analyses.

Nightly movements of female Striped Skunks during pre-parturition (mean = 4.2 km, SD = 4.9 km, n = 4), parturition/rearing (mean = 7.2 km, SD = 6.1 km, n = 19), pre-dispersal (mean = 5.6 km, SD = 3.0 km, n = 8), and dispersal (mean = 3.0 km, SD = 3.1, n = 2) were not statistically different ($F_{3, 29} = 0.70$, $P = 0.56$). Distance traveled during 12-h tracking sessions were variable and ranged from 0.0 to 20.3 km per night (mean = 6.2 km, SD = 5.2 km, n = 33 female-season). When we considered only one value for each female (weighted mean; average of all seasons), nightly movements averaged 7.4 km (SD = 5.9 km, n = 20 females).

During the parturition/rearing season, movements of males (mean = 6.7 km, SD = 3.2 km, n = 5) did not differ (t-test, df = 22, P = 0.84) from movement of females (mean = 7.2, SD = 6.1 km, n = 19). Movements of all skunks during the parturition/rearing period averaged 7.1 km (SD = 5.6 km, n = 24 skunks).

During spring and summer 1993 and 1994, we radio-tracked Striped Skunks for 1873 h (858 h in 1993, and 1015 h in 1994). During radio-tracking, we observed depredation of 10 duck nests (4 in 1993, 6 in 1994), thus averaging one depredation event for every 187 h of radio-tracking (1 for 215 h of radio-tracking in 1993, and 1 for 169 h in 1994). Observed depredation events were caused by 8 Striped Skunks (7 females, 1 male). Observed depredation events occurred between 9 June and 9 July in 1993, and between 15 May and 20 July in 1994.

From our observations, we extrapolated the number of nests depredated by a skunk during the duck nesting season. First, using our rate of discovery of 1 nest every 187 h of tracking, and allowing an average 8-10 h of foraging movements per night (Larivière and Messier 1997b), we estimated that individual skunks found 1 duck nest for every 19-23 nights of foraging. Considering the duck nesting season lasts approximately 60 d (mid-May until mid-July), then individual skunks may find 2-3 duck nests per season. However, because skunks foraging in dense vegetation may have depredated duck nests without us noticing, this estimate represents a minimum number, but our close-range observations (typically <50 m) and use of night-vision equipment suggests that we did not miss many depredation events.

Discussion

Our results clearly show that the foraging behavior of Striped Skunks consists of highly variable foraging movements and opportunistic, but infrequent, depredation of duck nests. The variable movements we observed within and among seasons, or between sexes, precluded detection of statistical differences. However, the trend suggested that movements were shorter during the pre-parturition season, higher during parturition season, and declined temporally thereafter. Interestingly, the decline in skunk movements over time coincides with the steady increase in availability of both small mammals and insects over time (Larivière and Messier 2000). Although we could not statistically link movements of skunks and food abundance because of only four sampling periods, we nonetheless observed apparently reduced skunk movements over time as prey abundance increased. An experiment done with simulated nests in our study area in 1995 indicated that increases in availability of food (chicken eggs) caused a reduction of activity and home ranges in female Striped Skunks (Larivière and Messier 2001a).

Movement rates observed in our study are the largest reported for this species. However, most previous studies of skunk movements relied on distance between consecutive den sites (Shirer and Fitch 1970), maximum distance from the den during any given night (Verts 1967), or distance between recapture sites (Bjorge et al. 1981). Our study is one of three that reported actual distance moved from telemetry locations. In Illinois, daily movements of Striped Skunks averaged 1.7 km for males (n = 4) and 1.4 km for females (n = 9) (Storm 1972). In North Dakota, nightly movements ranged from 0.0 to 9.3 km for 26 females (mean = 2.7 km), and from 0.4 to 10.5 km for males (mean = 3.3 km) (Greenwood et al. 1985). We believe our values are higher because we collected a more accurate description of movement paths by collecting locations at closer intervals (i.e., every 15 min) whereas animals were located every 2 h in North Dakota (Greenwood et al. 1985), and at intervals varying between 10 and 120 minutes in Illinois (Storm 1972).

Two additional explanations may explain the long movements of Striped Skunks in our study area. The first may be the composition of the landscape. Our study area was primarily cropland (66% of study area), a habitat that provides low abundance and diversity of foods for skunks (Larivière and Messier 2000). Not surprisingly, Striped Skunks in our study area avoided cropland when foraging (Larivière and Messier 2000). Thus, large amounts of cropland may contribute to increased movements as skunks were forced to travel across large fields to access prime habitats embedded therein. Nightly movements of Striped Skunks may be lower in large patches of continuous foraging habitats, a phenomenon that would help explain the typically higher nest success of ground-nesting birds in large patches of non-fragmented habitat (Pasitschniak-Arts and Messier 1996; Ball et al. 1995).

Another explanation may be related to the amount of food in the landscape. Possibly, food abundance may have been lower in our study area compared to previous studies, thus contributing to longer movements. Food supplementation experiments on Striped Skunks and other species typically yield lower activity, smaller ranges, and shorter foraging bouts (Boutin 1990; Larivière and Messier 1998a). However, because we have no way of comparing food abundance among studies, we can only speculate on whether differences existed between our study area and those used in previous studies.

Managers attempting to mitigate predation on duck nests need to know whether high predation rates occur because of specialized foraging by a few individuals depredating numerous nests, or simply by a high abundance of individuals each depredating only a few nests. Previous observations of skunk foraging behavior suggested that predation is incidental to foraging for other foods (Vickery et al. 1992; Larivière and Messier 1997a), and that greater predation rates are explained by a greater abundance of nest predators (Larivière and Messier 1998a).

Our study suggests that individual Striped Skunks in the Canadian prairies find between 0 and 3 duck nests per year. In fact, we observed only two skunks depredate more than one duck nest in any given year (both cases of females depredating two nests). Because our study area was located where nesting cover was common (managed nesting areas represented 9% of the study area), we believe our estimates probably are high because most areas of the Canadian prairies do not have 10% of the land as cover available for ducks, and hence probably hold fewer duck nests. Nonetheless, this suggests that availability of duck nests in the landscape is not high enough to warrant special foraging efforts; this reinforces the notion that nest depredation by Striped Skunks is strictly incidental (Larivière and Messier 1997a, 1998a, 2001b; Vickery et al. 1992). Finally, the rate of encounter suggests that the

impact of skunks on duck nests is directly related to skunk abundance, as was previously suggested (Larivière and Messier 1998a).

The impact of individual Striped Skunks on duck nests provides insight into the low success of management techniques that aim at educating individual predators. For example, conditioned-taste aversion had been unsuccessful under field conditions when mammals such as skunks and Raccoons were the main predators (Clark et al. 1996). We believe our data suggest that encounter rates with duck nests by individual predators are too low for such techniques to be effective, notwithstanding problems in causing aversion (Clark et al. 1996). At normal nest densities (<1 nest/ha), predators cannot subsist on eating duck eggs alone, and duck eggs only represent a marginal food item (Greenwood et al. 1999). Not surprisingly, foraging activity of Striped Skunks is directed at habitats where base prey such as insects and small mammals are most abundant, and not in areas managed for nesting ducks (Larivière and Messier 2000). Thus, management techniques that aim to increase nest success should be directed at reducing predator abundance locally (Garretson and Rohwer 2001), or reducing overall habitat suitability for predators with implementation of large-scale habitat programs through agricultural policies (e.g., Conservation Reserve Program in the United States, Reynolds et al. 2001).

Acknowledgments

This study was supported by the Prairie Habitat Joint Venture through a research grant from Ducks Unlimited (Institute for Wetland and Waterfowl Research), the Canadian Wildlife Service, as well as support from the Delta Waterfowl Foundation, the National Science and Engineering Research Council through and operating grant to SL, as well as postgraduate and postdoctoral fellowships from the Fonds pour la Formation de Chercheurs et l'Aide à la Recherche (FCAR), Québec. Field and laboratory assistance was provided by B. Dinter, E. Howard, G. Poon, B. Fry, K. Eade, H. Royer, P. Toner, S. Daviduik, and D. Anderson. J. Pitt, Y. T. Hwang, H. Nelson, and D. Murray reviewed earlier drafts of this manuscript. We followed a university-approved animal welfare protocol (#920091) while conducting this research.

Marczak, Laurie B., John S. Richardson, and Marie-Claire Classen. 2006. Life history phenology and sediment size association of the dragonfly *Cordulegaster dorsalis* (Odonata: Cordulegastridae) in an ephemeral habitat in southwestern British Columbia. Canadian Field Naturalist 120(3): 347–350.

The life cycle of the dragonfly *Cordulegaster dorsalis* was studied over one year by systematic sampling of larvae in three intermittent headwater streams in southwestern British Columbia. We determined that larvae normally take three years to reach maturity, emerging throughout July and August. There is limited evidence suggesting a split cohort development, with early emergence after two years. Additionally, we tested whether larval instars were distributed randomly or if they occupied different sediment microhabitats. Smaller animals tend to be associated with smaller grained organic sediments, although there was high variation between the streams.

Key Words: Odonata, dragonfly, *Cordulegaster dorsalis*, ephemeral stream, life history, phenology, British Columbia.

Dragonfly larvae are often conspicuous and important predators in stream ecosystems. In British Columbia, the family Cordulegastridae is represented by a single species, *Cordulegaster dorsalis* Hagen. Cordulegastrids occur in lotic waters, usually in small streams, where larvae live as shallow burrowers in sediment (Cannings 2002). In southwestern coastal British Columbia, larvae of *C. dorsalis* are often found in small headwater streams that are subject to extreme episodic drying. In the interior of the province, the species is less common and is mainly associated with small, spring-fed streams. Adults of *C. dorsalis* normally fly from mid-May to early September, peaking in July (Cannings 2002). Published accounts of the life history, habitat associations or ecological requirements of *C. dorsalis* in its larval stage are sparse.

Kennedy (1917) estimated *C. dorsalis* larvae in central California may require as many as four years to develop. The larval development of cordulegastrids in Europe ranges from 2 to 5 years and may include split cohorts (Ferreras-Romero and Corbet 1999). Split cohort timing has been documented in other species in the genus (*C. boltonii* [Donovan] in Ferreras-Romero and Corbet 1999). Corbet (1999: 230) maintains it is possible to identify a winter critical size, below which larvae in the first year of development will enter diapause during the subsequent summer period, requiring another year's growth to reach metamorphosis. Such differential growth rates within a single cohort may be produced by staggered egg-laying times, food limitation or variability in the environment. Given the transitory nature of the streams used by *C. dorsalis*, it is possible that it exhibits plasticity in growth rates and emergence times in response to continual shrinking and rewetting of the streams.

Dragonfly larvae increase in size by three to four orders of magnitude as they develop. Microhabitat selection may have much to do with the physical constraints of size. Different species of burrowing odonates prefer certain sediment-size categories (Corbet 1999). *C. boltonii* has sediment-size preferences that vary with specific larval size classes (Prodon 1976 unpublished dissertation referenced in Corbet 1999). In contrast, *C. maculata* Sélys in Virginia is a habitat generalist, occuring in equal densities in both silts and sands (Burcher and Smock 2002). In general, small larvae of *C. boltonii* prefer much finer sediments than do larger larvae – larvae tend to select a particle size that offers the least obstruction to burrowing (Corbet 1999).

We report life-history observations (morphological measurements) of larval *C. dorsalis* over a one year period in three small headwater streams subject to late summer drying. We observed that large and small larvae did not occur together within pools. At the same time, we observed surprisingly high densities of odonate larvae in small, shrinking pools during late summer. We tested whether small and large larval instars occupy different sediment microhabitats and report life-history observations (morphological measurements) of larval *C. dorsalis* over a one-year period in three small headwater streams subject to late summer drying.

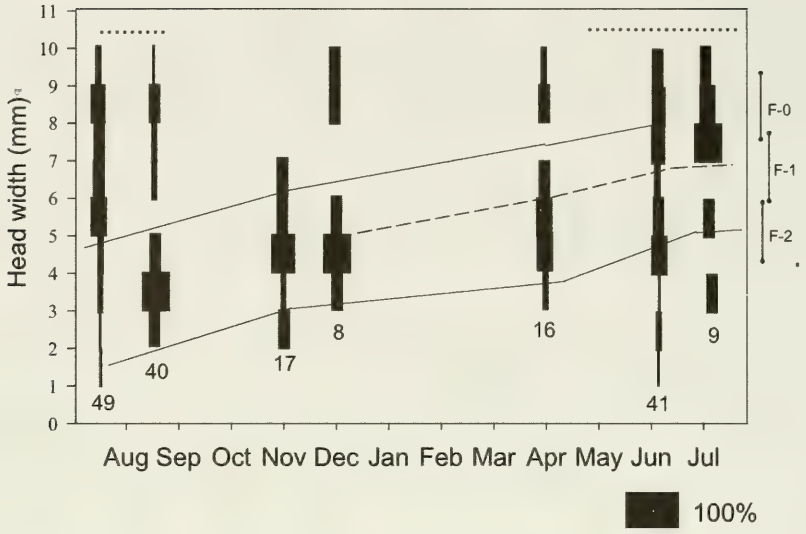

FIGURE 1. Life history patterns of *Cordulegaster dorsalis* shown for 2002-2003 — in G Creek (n = 175). Continuous lines ascending from left to right indicate inferred boundaries between successive hatching cohorts. The emergence period during late summer is shown (dotted line). Size ranges of the last three instars are indicated. The broken line indicates an alternate interpretation and represents the inferred boundary between the two components that could result from cohort-splitting in the two-year-old hatching cohort, thus distinguishing larvae that grow fast (above line) and slowly (below line). Numbers below columns indicate sample sizes for each sampling date. Widths of black bars for each interval of headwidth on a given date represent the relative fraction of the total sample that fell in that interval; total possible width for any given sampling date is represented by the black legend box labelled 100%.

Methods

Study Site

This study took place in the 5157 ha Malcolm Knapp Research Forest, located in Maple Ridge, British Columbia. The forest is located in the Pacific coastal rain forest, with a maritime climate of cool dry summers and warm wet winters (Naiman et al. 2000). We sampled *Cordulegaster dorsalis* larvae for life history characteristics and sediment associations in three streams within the forest (I, F and G streams; 49°18'40"N, 122°32'40"W), which were part of an ongoing riparian management experiment (see Kiffney et al. (2003) for site descriptions). Both F and G streams retained a 10 m forest buffer while I stream flowed through a 5-year-old clearcut. The dominant vegetation surrounding these creeks included Red Alder (*Alnus rubra*) and Vine Maple (*Acer circinatum*) with a canopy composed largely of Western Hemlock (*Tsuga heterophylla*), Western Redcedar (*Thuja plicata*) and Douglas-fir (*Pseudotsuga menziesii*). Vegetation adjacent to I stream consisted of shrubs, particularly Salmonberry (*Rubus spectabilis*) and Huckleberry (*Vaccinium ovatum*).

Life-history characteristics

We surveyed approximately 200 m each of I, F, and G streams in August, October and December of 2002 and April, July and August of 2003, collecting larvae using dip nets and hand sorting. We measured head width (Hdw max. distance between the lateral margins of the compound eyes), total body length (Tbl; max. distance between the mouthparts and the end of the cerci measured along the dorsal surface) and wingpad length to the nearest 0.1 mm with vernier-scale callipers. Using regression analysis we determined the scaling coefficient (reported as the slope of the line) for head width and body length. Size ranges of late instar classes were determined from the relationship between wingpad length and head width. Year class separation was analysed using wingpad to head width relationships together with visual assessment of size frequency distributions (after Ferreras-Romero and Corbet 1999). The level of significance was set at $P = 0.05$.

Sediments

The habitat associations of different size classes of larvae were characterized from August 2002 through April 2003. Sediment samples were collected at each point of larval capture and sieved into six size fractions (63 µm, 250 µm, 500 µm, 1 mm, 2 mm, 4 mm). Each sediment fraction was air-dried and weighed, then ashed at 550°C for 2 h and reweighed to obtain weights of both inorganic and organic fractions. Cumulative percent curves were used to determine the median particle size of each sample. We used linear regression to investigate the data for relationships between larval head width, median sediment size and organic fraction.

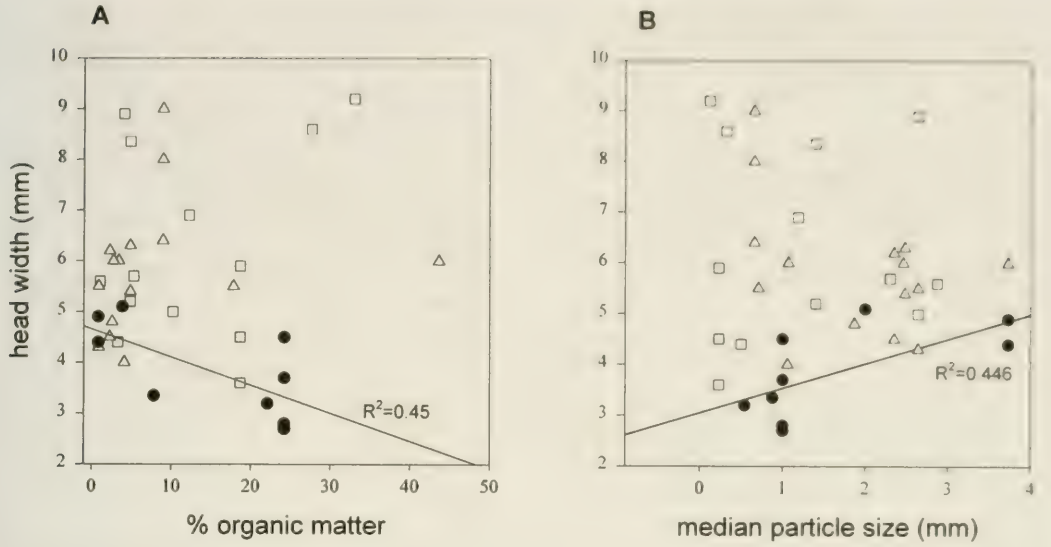

FIGURE 2. Relationship between larval head width of *Cordulegaster dorsalis* and sediment characteristics — (A) percentage of organic matter; and (B) median particle size. Regressions were significant for F Creek (closed circles) but not for G Creek (open squares) or I Creek (open triangles).

Results and Discussion

During August 2003 when sample sizes were largest, head width of F-0 (7.5 mm – 9.2 mm) and F-1 (6 mm – 7.8 mm) larvae overlapped, but wingpad lengths were discrete (3 mm – 5.5 mm in F-2, 6.9 mm – 10 mm in F-1 and 11.9 mm – 15.5 mm in F-0). Total body length and head width were correlated ($R^2 = 0.86$, $P < 0.001$, TBL = 4.49 HW – 0.59).

In G Creek, larvae of *Cordulegaster dorsalis* – derived from eggs that likely hatched in early summer – grew through late summer and early autumn (Figure 1). At the beginning of their second year most larvae had a head width between 2 mm and 5 mm. At the end of their second year of growth, larvae achieved headwidths between 5 mm and 8 mm. Emergence occurred at head widths greater than ca. 8 mm during July and August of the third year.

The pattern of development that we observed in G Creek (where sample size was greatest, $n = 180$) indicated that, in general, *C. dorsalis* larvae require three years to achieve metamorphosis. It is possible to interpret these data as evidence of a split-cohort in the second year with a "fast" group of larvae emerging following accelerated late summer to early fall growth at the end of their first year (Figure 1, dashed line). This interpretation would suggest a winter critical size of ca. 6 mm (Hdw; Figure 1). Sample sizes were too small in I Creek ($n = 30$) and F Creek ($n = 21$) to bolster a split-cohort interpretation; the Hdw of collected larvae generally support a three-year development.

Many Odonata retain a synchronized emergence period through the use of photoperiod cues (e.g. Aoki 1999; Burcher and Smock 2002). Some species of odonates appear to have both "slow" and "fast" components of the same cohort (Martin et al. 1991; Johnson et al. 1995; Ferreras-Romero and Corbet 1999). We present two possible development schedules for *C. dorsalis*: a split cohort with a "fast" component emerging after two years and a "slow" component requiring three years to complete development. Cordulegastridae are noted for their protracted larval development, a pattern that might be anticipated of shallow burrowers occupying small, cool streams (Corbet 1999). Two years would represent a remarkably short development time within this family, particularly given the known four-year development time for cordulegastrids in northern California (Kennedy 1917). A more complete record of larval growth rates is required before evidence of a slow and fast development in *C. dorsalis* can be dismissed; in the meantime, the data most strongly support a simple three-year development schedule.

During our surveys for larval development, we observed that small pools seldom contained both large and small larvae. Larvae were most abundant at median particle sizes between 1.5 mm and 2.5 mm. The head width of larvae was negatively associated with percent total organic content in F Creek (Figure 2a; $P < 0.01$; $R^2 = 0.451$) but no relationship was evident in either G or I creeks. Similarly, the head width of larvae was positively associated with median particle size in F Creek (Figure 2b; $P < 0.05$; $R^2 = 0.446$) while no relationship was evident in either G or I creeks. It should be noted that median particle and percent

organic matter are not independent measures; there is a negative correlation (r = –0.699). Post-hoc power analysis suggested that these results must be interpreted cautiously (*power* = 0.5134 organic; 0.5072 median particle).

All odonate larvae are opportunistic predators that will eat almost any type of prey they can detect and subdue (Burcher and Smock 2002). Since larger larvae will eat smaller larvae when they encounter them, it seems plausible that some form of habitat partitioning occurs to minimize intraspecific competition and cannibalism. How larvae are distributed at the microhabitat scale will largely determine the frequency of their interactions with conspecifics, affecting the probability of agonistic interactions. The presence or absence of other predators, such as fish, may also affect the microdistribution of larvae. Suhling (1999) demonstrated that small larvae of the gomphid, *Onychogomphus uncatus* (Charpentier), were significantly more abundant in sand where fish predation was also lowest while medium-sized and large larvae were most abundant in gravel and stones, respectively.

In our study, smaller larvae appeared to be associated with finer sediments with a higher organic fraction. There was a trend supporting larval size sorting relative to sediment microhabitats; however, these results must be interpreted conservatively since this pattern was evident in only one of the three streams surveyed and overall sample sizes were low. In previous habitat surveys of this genus, larvae of *C. bidentata* Sélys were most abundant at a mean grain size of 2.04 mm while *C. heros* Theischinger were most abundant at 2.79 mm (Lang et al. 2001). This is consistent with our finding that larvae of *C. dorsalis* were most abundant within medium sand sediments with a median grain size between 1.5 mm and 2.5 mm.

Although *C. dorsalis* larvae prefer smaller sediments as a group, our evidence is inconclusive regarding microhabitat partitioning amongst larval size classes. There are several alternative explanations for the size sorting we observed between small pools. Larvae may become trapped in these shrinking habitats in a nearly random fashion with respect to size, and the apparent sorting occurs post hoc through intraspecific predation. Smaller larvae would only survive in pools that have a low proportion of late instar larva when these habitats become isolated. Alternatively, the observed size sorting of large and small larvae may relate to a factor that is strongly correlated with sediment grain sizes such as current speed or oxygen levels.

Carbyn, S., P. M. Catling, S. P. Vander Kloet, and S. Basquill. 2006. An analysis of the vascular flora of Annapolis Heathlands, Nova Scotia. Canadian Field-Naturalist 120(3): 351–362.

A description and analysis of the vascular plant composition of heathlands in the Annapolis valley were undertaken to provide a basis for biodiversity preservation within a system of protected sites. Species presence and abundance were recorded at 23 remnant sites identified using topographic maps, air photos, and Nova Scotia Department of Natural Resources records. A total of 126 species was recorded, of which 94 were native and 31 introduced. The Annapolis heathland remnants are strongly dominated by *Corema conradii* with *Comptonia peregrina*, *Vaccinium angustifolium* and *Pteridium aquilinum* var. *latiusculum*. A number of species, including *Solidago bicolor*, *Carex tonsa* var. *rugosperma*, *Dichanthelium depauperatum*, *Lechea intermedia*, *Melampyrum lineare*, and *Rubus hispidus*, were characteristic of heathland remnants, although they usually contributed little to the total cover. The most frequent alien species were *Hieracium pilosella* and *Festuca filiformis*, but *Pinus sylvestris*, present at 7 of 18 sites, appeared to have the greatest impact in displacing native species. Species listed as at risk and sensitive in Nova Scotia, including *Helianthemun canadense*, *Hudsonia ericoides* and *Viola sagittata* var. *ovata*, occur in open disturbed sand in the *Corema* heathlands. Distinctive patterns of variation occur in several species and variation in crop relatives is noted with particular reference to the genera *Rubus* (blackberries), *Amelanchier* (Juneberries, Saskatoon) and *Vaccinium* (Blueberries). The available evidence suggests that the heathlands and sandy barrens in the Annapolis valley differ from those further west in Canada and from anthropogenic and coastal heathlands of Nova Scotia in their species composition including particularly the presence of *Corema conradii*, *Hudsonia ericoides* and *Amelanchier lucida*. The need to protect representative examples is supported.

Key Words: Heathlands, Annapolis valley, barrens, vascular plants, flora, Corema, Nova Scotia, Canada.

In 1921, legendary Harvard botanist Merritt Lyndon Fernald visited the Annapolis valley. He found extensive open heathlands. He noted: "near Berwick and from there to Wilmot were vast uncultivated plains carpeted, wherever dry enough, with a close growth of the New Jersey Pine barren *Corema conradii*, and, ... remnants of them near Middleton" (Fernald 1921). As recently as the 1960s open heathlands with scattered Red Pines (*Pinus resinosa*) occurred for many miles along the Evangeline Trail (Figure 1). It has been estimated that in pre-settlement times the actual area of heathland encompassed approximately 200 km^2. Today less than 3% of the original heathland vegetation remains in the Annapolis Valley (Catling et al. 2004), and even that is threatened by loss of natural ecological processes, invasive species and conversion of the landscape (Catling et al. 2004; Catling and Carbyn 2004). Protection of this ecosystem is important for the protection of (1) insect pollinators of adjacent crops; (2) protection of wild relatives of crops for crop improvement; (3) benchmark research examples; (4) teaching examples; (5) nature-related recreational opportunities; and (6) protection of biodiversity generally in connection with national and international accords. The only descriptions of Annapolis heathlands currently available (Fernald 1921; Roland 1946; Catling et al. 2004) are brief, non-quantitative, and insufficient as a basis for protection of biodiversity. Here we provide a description of remnants of natural heathland in the Annapolis Valley along with an indication of dominant species, rare and significant species, variation between sites and relationship to other eastern Canadian sand barrens. This is designed to provide a basis for further study and for the establishment of a system of protected sites.

Methods

Sites and data

The study area consists of 23 sites in the Annapolis Valley (Table 1, Figure 2). Sites are defined as areas surveyed separated by at least 0.5 km. Information from the Nova Scotia Department of Natural Resources and topographical maps were used to determine the most probable locations of heathland vegetation occurring on sandy soil.

At sites 1–19 abundance of vascular plants was recorded. Areas surveyed varied from approximately 0.5–61 hectares in extent. The majority of these 19 sites

FIGURE 1. Open heathland dominated by *Corema conradii* (Broom Crowberry) with *Pinus resinosa* (Red Pine). Photo by P. M. Catling in 2004 at site 8.

were visited on at least two occasions in 2003, with one visit in early summer and another in autumn. Approximately two hours were spent at each site on each visit. Species lists were made at each site (Table 2). An abundance value ranging from 0–5 was assigned to each species (1 = rare, 2 = uncommon, 3 = common, 4 = frequent and locally dominant, 5 = dominant) based on consensus of two or three observers. Although some larger sites were visited more often, almost all species recorded were recorded in the first hour of two visits. Time spent at sites was therefore considered to be adequate and the lists are thought to be essentially

complete. Voucher specimens collected at various sites were deposited in the vascular plant herbarium at Agriculture Canada in Ottawa (DAO). Status of plant species was determined by using Maher et al. (1978), the recent listing of species at risk (Nova Scotia Department of Natural Resources 2001*) and information and lists on file at the Atlantic Conservation Data Centre in Sackville.

At sites 20–23, plant association sampling methods were employed following provincial plot standards (Quigley et al. 2005*) and Canadian vegetation classification conventions (CNVC Technical Committee 2004*). In May of 2005, at each of the four sites, a four hundred square meter plot was subjectively placed in a homogeneous tract of heathland vegetation, where canopy tree cover exceeded 10 percent. The sampled association was the open woodland stage of the Annapolis Valley sand plain. Species and cover values, representing percentage of plot area within a vegetation layer, were visually assessed for five life forms (Table 3). Lichen names follow Esslinger (1997*), bryophyte names follow Anderson et al. (1990), and vascular plant names are from Kartesz and Meachum (1999).

Although many voucher specimens were collected (and deposited at DAO), a sufficient number of specimens of the genus *Aronia* were not collected to enable a determination of which species (or hybrid) was present at a particular site. Thus only the genus name appears in Table 2. Although *Rosa carolina* and *Rosa virginiana* were noted, both may have been present at any site where either was recorded, and some intermediates were noted. *Rubus hispidus* may be over-represented in the survey and *Rubus arenicola* may be under-represented due to difficulties in distinguishing these, and hybrids between them may also have been present.

Results and Discussion.

Native species and limitations of the vegetation description

Although 104 native species are recorded from the 23 sites surveyed, and although these sites covered a rather extensive area, they were mostly drier examples of dry, open sandy habitats (Figure 1). The relatively short-lived wetter examples and those associated with natural disturbances, such as fire, are now much less common than the drier examples. Thus as a reconstruc-

tion of the Annapolis sand barren flora, the mesic and successional stages of dry barrens are to a large extent omitted. This may explain the lack of some species in the survey, such as *Agalinis neoscotica* (Greene) Fern. (Middleton False Foxglove), which was described from Annapolis heathlands near Middleton, and also *Bartonia virginica* (L.) BSP., *Carex atlantica*, *Polygala sanguinea* L. and *Sisyrinchium fuscatum* Bickn. All of these species occur on heathlands near Middleton (personal observation), but were not seen during the present survey. Their abundance in the area in the past (Fernald 1921, page 138) suggests that the more mesic and naturally disturbed areas were much more prevalent only a short time ago. Fernald (1921) referred to these as the "the damper Polytrichim-carpeted areas." He noted that "*Bartonia virginica* was everywhere," but it was not recorded in any of the barrens in our survey and only our site 10 approached this damper sand barrens habitat.

In addition to the lack of mesic sites it is of interest that in two days in 1920 Fernald (1921) recorded two species from the drier heathlands near Middleton that were not seen by us. These were *Potentilla tridentata* and *Pyrola rotundifolia*. Although our data indicate the general and dominant composition of the Annapolis heathlands, the differences with Fernald's brief survey suggest that it may never be possible to have a complete knowledge of their former floristc composition.

Dominant vascular plants

Relatively few of the 126 species (94 were native and 31 introduced – Table 2) present in the 19 completely surveyed sites were dominant in the vegetation. Species present at all sites included *Corema conradii*, *Danthonia spicata*, *Pinus strobus* and *Solidago bicolor*. Species present at 18 of the 19 sites were *Amelanchier laevis*, *Carex tonsa* var. *rugosperma*, *Comptonia peregina*, *Dichanthelium depauperatum*, *Pteridium aquilinum* var. *latiusculum*, *Vaccinium angustifolium* and *Populus tremuloides*. Species with the highest overall cover values included *Corema conradii* with 91 followed by *Comptonia peregrina* with 59, *Pteridium acquilinum* var. *latiusculum* with 57, and *Vaccinium angustifolium* with 56. A number of species, including *Solidago bicolor, Carex tonsa* var. *rugosperma*, *Dichanthelium depauperatum*, *Lechea intermedia*, *Melampyrum lineare* and *Rubus hispidus*, were characteristic of heathland remnants, although they were rarely dominant. The most frequent alien species were *Hieracium pilosella* and *Festuca filiformis*, both at 17 and 16 (respectively) of 19 sites. The most serious invasive of the heathlands in terms of displacing native species was *Pinus sylvestris*, present at 8 sites (Catling and Carbyn 2004).

The more wooded plot sites (20–23) gave a very similar picture of the *Corema*-dominated heathland, but with scattered trees, mostly *Pinus resinosa* (Table 3, Figure 3). Three species more often associated with woodland than with barrens (*Clintonia borealis*, *Lyco-*

FIGURE 3. Open wooded heathland dominated by *Corema conradii* and *Cladina rangiferina* with scattered *Pinus resinosa*. Although there is much open area, the site exceeds the threshold 10% tree cover required for classification as a treed association under Canadian vegetation classification conventions (CNVC Technical Committee 2004*). Photo by S. Basquill on 25 May 2005 at site 20.

podium obscurum and *Oryzopsis asperifolia*) were present a these more wooded sites. Although vascular plants were the focus of the descriptive work, the plot data included lichens and bryophytes, suggesting the former (*Cladina rangiferina* and *C. stellaris*) to be a significant component. This suggestion is supported by general observations at the 19 other sites where quantitative data on bryophytes and lichens was not obtained.

Although Roland (1946) described the Annapolis sand barrens and heathlands 60 years ago, his description, which recorded 35 species, corresponds very closely to the composition seen in the relicts that remain today. The successional processes are possibly also the same as described generally by Roland, but succession may have been much more rapid in some areas than in others where barrens and heathlands may have existed as a subclimax lasting for centuries, even without fire. Roland's article was written at a time when sand barrens, heathlands and savanna were regarded as wasteland rather than as special places for native biodiversity, but his strong forestry theme is accompanied by many astute observations regarding the native flora. At the time of early settlement the barrens and heathlands may have expanded due to cutting and burning of pine forests and abandonment of sandy land cleared for agriculture as suggested by Roland. However there is little doubt that they also existed in pre-settlement times.

Rare and significant species

The only species considered to be at risk in Nova Scotia that occurs in the Annapolis heathlands is *Helianthemum canadense* (Long-Branch Frostweed, Figure 4). It was found at 6 of the sites, always in disturbed habitats with some bare sand. Both *Viola sagittata* var. *ovata* and *Hudsonia ericoides* are listed as sensitive (Nova Scotia Department of Natural Resources 2001*), and these also occurred in disturbed sandy areas (Figure 5). The provincially rare (Maher et al. 1978) *Sisyrinchium fuscatum* Bickn. (Coastal-Plain Blue-Eyed-Grass) was reported from "sandy areas near Middleton" (*sub Sisyrinchium arenicola* Bickn., Roland and Smith 1969), but was not seen during the present survey.

In addition to the rare and threatened species there is a suggestion of some distinctive patterns of variation due to taxonomic recognition of several variants. Among these is a sand barren ecotype of *Amelanchier lucida* (personal observation). Taxa of blackberries (*Rubus particeps, R. arenicola*), although not recognized as discrete in some recent literature, have been reported from the Annapolis heathlands suggesting at

least the presence of distinctive genetic variants within broadly defined species. Further study may indicate both of these to be worthy of taxonomic recognition. A restricted glabrous variant of *Viola sagittata* var. *ovata* (f. *glabrata*) occurs on the dry open sand with the more typical form. Three taxa have been described from Annapolis heathlands: *Amelanchier lucida* Fernald, *Dichanthelium (sub Panicum) depauperatum* var. *psilophyllum* f. *cryptostachys* Fernald, and *Rubus particeps* Bailey.

The heathland ecosystem is particularly valuable as a reservoir of genetic variation in crops and crop relatives. Fernald (1921) commented on the remarkable variation in wild blueberries (*Vaccinium angustifolium* and *V. myrtilloides*) in Annapolis heathland remnants near Middleton. In addition to blueberries (Table 2) there are potential genotypes of Aronia (*Aronia* sp.), of blackberries (*Rubus hispidus* and others), juneberries (*Amelanchier lucida* and *A. laevis*), huckleberries (*Gaylussacia baccata* and *G. dumosa*), cherries (*Prunus pensylvanica*, *P. virginiana*, and *P. serotina*) and a strawberry (*Fragaria virginiana*).

Variation between sites

Although all sites shared dominant species (Table 2) they varied in diversity from 26 to 57 native species. Much of the variation between sites appeared to be attributable to disturbance and soil moisture. Those sites with lower lying and periodic moist areas and open sand had the highest vascular plant diversity. Site 10 for example was the most unlike the other sites in native species composition, possibly a result of parts of it having a relatively high water table and disturbed areas of periodically moist sand where dry ground species such as *Carex tonsa* var. *rugosperma* and *Danthonia spicata* occurred with wetland species such as *Drosera intermedia*.

Characteristic native species and "at risk" or "sensitive" species were present at some sites but absent from others (Table 2). Sites also varied in the extent to which alien species were present and dominant (Table 2). For example parts of sites 1 and 4 had extensive and spreading stands of *Pinus sylvestris*, but displacement of native vegetation by this introduced tree was either less extensive or not observed at other sites. *Festuca filiformis* was a co-dominant at site 5 but not elsewhere.

Species presence, diversity and extent of impacts all require consideration in selecting sites for protection. The variation between sites in composition and abundance, including that of rare and/or characteristic species, suggests that protection of a number of sites will be necessary to protect representative ecosystem components.

Relationship to other heathlands and barrens

In Canada, *Corema*-dominated barrens are characteristic of the maritime region. *Corema conradii* has a restricted distribution extending from the Gulf of St. Lawrence region south to New Jersey. It does not occur in sand barrens further to the west in Canada, for example in the Ottawa valley, where *Vaccinium angustifolium* is the dominant heath shrub accompanied by other shrubs such as *Prunus susquehanae* and *Comptonia peregina* (Carbyn and Catling 1995). Other species present in the Annapolis heathlands but absent in Ottawa valley sites were *Amelanchier lucida, Deschampsia flexuosa, Rubus hispidus* and *Solidago bicolor*. Among the prevalent species in Ottawa valley sand barrens but absent in the Annapolis sites were *Carex siccata, Carex lucorum, Dichanthelium sabulorum* var. *thinium, Polygonella articulata* and *Prunus susquehanae* (Carbyn and Catling 1995).

FIGURE 4. *Helianthemum canadense* (Long-Branch Frostweed), a native plant at risk in Nova Scotia, with its main Nova Scotian occurrence on the Annapolis valley heathlands. Photo by P. M. Catling in 2004 at site 8.

Within Nova Scotia, "barrens" with heath vegetation occupied a large part of the western portion of the province (Strang 1972). Some of these barrens are a short-lived successional stage following fire, whereas in other cases they are long persisting. Those of short duration have in some cases been produced by cutting and then maintained by fires. Two such barrens were described by Hall and Aalders (1968). Such barrens, produced by human activities, have been considered a degraded landscape of little economic value. The existence and importance of apparently natural barrens have only recently become apparent (Catling et al. 2004). The sites described by Hall and Aalders (1968) differ from those in the Annapolis Valley in lacking *Corema conradii*, the dominant of the Annapolis barrens. They were also without several other species, including *Hudsonia ericoides*. On this basis the differences between man-made and natural barrens seem

FIGURE 5. Open sandy ground in a disturbed area of heathland with *Comptonia peregrina* (Sweet Fern) and *Viola sagittata* var. *ovata* (Arrow-leaved Violet). Photo by P. M. Catling in 2004 at site 8.

pronounced, but with only two anthropogenic sites, a more detailed comparison is unnecessary.

The apparently longer persisting natural barrens in Nova Scotia are readily divided into two major vegetation types based on either granitic or sandy substrates (personal observation). Sandy heathlands like those of the Annapolis Valley were also well developed in the interior of Yarmouth County and near Debert, Springhill, Parrsboro, and on coastal dunes in Guysborough and Kings counties and on Sable Island. The coastal heathlands on sand differ from the interior sites in both species composition and species abundance, and the differences suggest adaptation to different conditions. Differences also exist at the infraspecific level. For example *Lechea intermedia* var. *intermedia* occurs in interior heathlands while *L. intermedia* var. *juniperina* occurs on the coastal sandy heathlands. The heathlands on Sable Island appear distinct (Catling et al. 1985). The interior sandy heathlands also appear to vary regionally, presumably due to differences in climate. The climate in southern Yarmouth and Shelburne differs from that of the Annapolis Valley (personal observation). The data suggest that the Annapolis heathlands are distinctive in their floristic composition.

Acknowledgments

Mark F. Elderkin, Species at Risk biologist with the Nova Scotia Department of Natural Resources, assisted with current information on status ranks. Lawrence Benjamin and Randy Milton, also of the Nova Scotia Department of Natural Resources, provided information on site locations for rare plant species in the Annapolis Valley. Steve Javorek and M. Grant assisted with field studies (site 1). Geoff Mercer assisted with the inventory of sites on military bases at Aldershot (site 14) and Greenwood (sites 17 and 18).

Pacific Hagfish, *Eptatretus stoutii*, Spotted Ratfish, *Hydrolagus colliei*, and Scavenger Activity on Tethered Carrion in Subtidal Benthic Communities off Western Vancouver Island

SARAH DAVIES[1], ALI GRIFFITHS[1], and T. E. REIMCHEN[2]

[1]Bamfield Marine Sciences Centre, Bamfield, British Columbia V0R 1B0 Canada
[2]Department of Biology, P.O. Box 3020, University of Victoria, Victoria, British Columbia V8W 3N5 Canada; e-mail: reimchen@uvic.ca (corresponding author)

Davies, Sarah, Ali Griffiths, and T. E. Reimchen. 2006. Pacific Hagfish, *Eptatretus stoutii*, Spotted Ratfish, *Hydrolagus colliei*, and scavenger activity on tethered carrion in subtidal benthic communities off Western Vancouver Island. Canadian Field-Naturalist 120(3): 363–366.

The influence of pelagic carrion food falls on marine benthic scavenging communities was investigated at two depths (10 m, 50 m) in Barkley Sound, west Vancouver Island, British Columbia from 12 May to 4 June, 2003. A remotely operated vehicle (ROV) equipped with video cameras was used to monitor anchored carrion (15 kg pig leg) during daylight and darkness. The videos were subsequently analyzed for species diversity, abundance and the intensity of scavenging. At 10 m, Redrock Crab (*Cancer productus)* and Kelp Greenling (*Hexagrammos decagrammus)* dominated, while at 50 m, Spot Shrimp (*Pandalus platyceros),* Spotted Ratfish (*Hydrolagus colliei)* and Pacific Hagfish (*Eptatretus stoutii)* were the dominant species, most of which were nocturnal. Hagfish were the major consumers of the carrion and after 23 days, no soft tissues remained at 50 m while 40% remained at 10 m. Within 24 hours of the carrion deployment, two of eleven ratfish succumbed, probably due to the direct clogging effects of hagfish mucus on the respiratory apparatus of the ratfish. These field observations are consistent with laboratory results suggesting high efficacy of hagfish mucus in competitive interactions.

Key Words: Pacific Hagfish, *Eptatretus stoutii,* Spotted Ratfish, *Hydrolagus colliei,* Spot Shrimp, *Pandalus platyceros,* Redrock Crab, *Cancer productus,* Kelp Greenling, *Hexagrammos decagrammus,* marine scavengers, carrion, remotely operated vehicle (ROV), nutrient cycling, Vancouver Island, British Columbia.

Vertebrate carcasses provide an episodic but highly important food source for benthic organisms, particularly at depths beyond the zones of primary productivity (Lalli and Parsons 2001). Such carcasses have recently become of interest due to increasing discards in fisheries as this may shift benthic community structure (Collins et al. 1999). Species such as ratfish and benthic sharks as well as crustaceans may benefit from such food falls (Collins et al. 1999; Tamburri and Barry 1999). There are few descriptions of the scavenging community or the interactions among species around these carcasses.

We anchored carrion at two depths (10 m, 50 m) in Barkley Sound, west Vancouver Island, British Columbia and monitored the carrion with a remotely-operated vehicle (ROV). We provide here an examination of scavenger diversity, abundance and interactions among species during daylight and darkness.

Methods

Two soft-substrate sites (10 m, 50 m: 48°50'N, 125°10'W) in Mackenzie Anchorage, Barkley Sound, British Columbia were chosen and single 15 kg pig legs (frozen with intact skin) were anchored at each site. Initial deployment occurred at 1030 h on 12 May 2003. An ROV (Deep Ocean Engineering Phantom HD2+) equipped with 5mW 635 nm lasers (10 cm standard for scaling) and 250W Tungsten-Halogen lights were used to monitor the carrion. The ROV was stationed beside the carrion for 30 minutes during night trials and 15 minutes (due to less activity) during day trials. We switched the ROV lights off for 1-2 minutes on several occasions during the night monitoring phase but observed no changes in activity. Before surfacing with the ROV, areas within 5 m of carrion were scanned for individuals. Day trials of the ROV were carried out near 1400 h and replicated on three occasions (13, 14, 16 May) while night trials occurred near 2230 h and were replicated on four occasions (12, 13, 14, 23 May). The experiment was terminated on 4 June and the two carcasses returned to the surface and relative tissues were estimated. Twelve hours of videotape were analyzed. Percent of remaining carrion and sizes of scavengers were estimated from the laser standards. Species were identified and all individuals within several metres of the carrion were counted. General behavior of the species was noted. Paired sampled t-tests were used to test for significant differences for species and abundance between sites and within sites.

Results

Species Abundance

Carrion anchored at the two depths attracted a different assemblage of species (Figure 1). At 10 m, Redrock Crab (*Cancer productus)* (7-20 cm), and Kelp Greenling (*Hexagrammos decagrammus)* (11-23 cm)

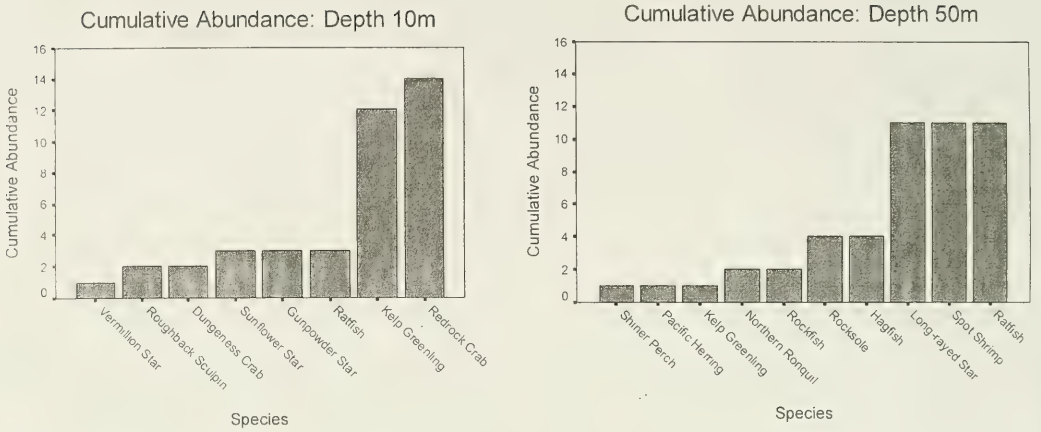

FIGURE 1. Cumulative species abundances of scavengers observed at carrion anchored at 10 m and 50 m in Barkley Sound, Vancouver Island.

were the dominant species, while at 50 m, Long-rayed Star (*Stylasterias forriei)* (20-60 cm), Spot Shrimp (*Pandalus platyceros)* (12-20 cm), Spotted Ratfish (*Hydrolagus colliei)* (18-25 cm), Pacific Hagfish (35-65 cm) and Rocksole *(Lepidosetta bilineata)* were dominant. Only two of 16 species (Spotted Ratfish, Kelp Greenling) were common to both sites (Figure 2). Although all species were in direct contact or immediately adjacent to the carrion, only six species actively foraged off the carrion (Pacific Hagfish, Redrock Crab, Dungeness Crab (*Cancer magister*), Sunflower Star (*Pycnopodia helianthoides)*, Long-rayed Star (*Orthasterias koehleri)*, and Spot Shrimp). Hagfish undertook extensive burrowing and excavations and were the major consumers of tissues. Ratfish swam commonly in close vicinity to the carrion but we observed no foraging activity. Daily consumption rates at 10 m were initially high and then decreased while at the 50 m site, the rate increased throughout the duration of sampling. On the last ROV survey (Day 23), 40% of the soft tissues remained at the 10 m site while only bone remained at the 50 m site.

Diel variations

The scavenger community differed during daylight and darkness (Figure 3). At both sites there were increased numbers of species observed during darkness (10 m Day, 5 , Night, 11; 50 m Day, 5, Night, 9). At 10 m depth, nocturnal scavengers were Redrock Crab, Spotted Ratfish, Roughback Sculpin (*Chitonotus pugetensis)*, and Dungeness Crab. At 50 m, Long rayed Star was present in both day and night trials and was seen continually in all surveys. Northern Ronquil (*Ronquilus jordani)*, Rocksole and Kelp Greenling were seen only during day trials. Pacific Hagfish, Spotted Ratfish, and Spot Shrimp were dominant at night.

Behavioural interactions within and among scavenger species

Diverse interactions occurred among species. Redrock Crabs defended the carrion by direct attacks against conspecifics as well as against Kelp Greenling. Pacific Hagfish excavated burrows within the carrion by rasping, full-body spinning and occasional knotting. Spotted Ratfish swam in close vicinity to the carrion and in several instances directly contacted the hagfish but we saw no evidence of agonistic behaviour. However, during the second ROV flight, we observed two freshly deceased ratfish lying within several meters of the carrion. There was no evidence of external damage to either ratfish but there was extensive subsurface haemorrhaging around the mouth on one ratfish and strands of mucus on the second and we infer rapid respiratory failure from the hagfish mucus that was prevalent in the water column around the carrion. During the ROV survey, hagfish did not feed on dead ratfish. Strands of mucus that separated from hagfish when feeding on the carrion were very adhesive as the strands disabled thruster motors of the ROV.

Discussion

High productivity and the recycling of nutrients sustain large populations of benthic organisms in the waters of the continental shelf (Nybakken 2001). We examined an experimental food fall at two (10 m, 50 m) natural habitats in coastal British Columbia and found that species assemblages differed between depths and with diel variation. The intensity of scavenging was greater at increased depth and increased during night, which corroborates well with other observations on scavenging communities (Collins et al. 1999). Shifts in diel patterns to nocturnal activity are common in marine

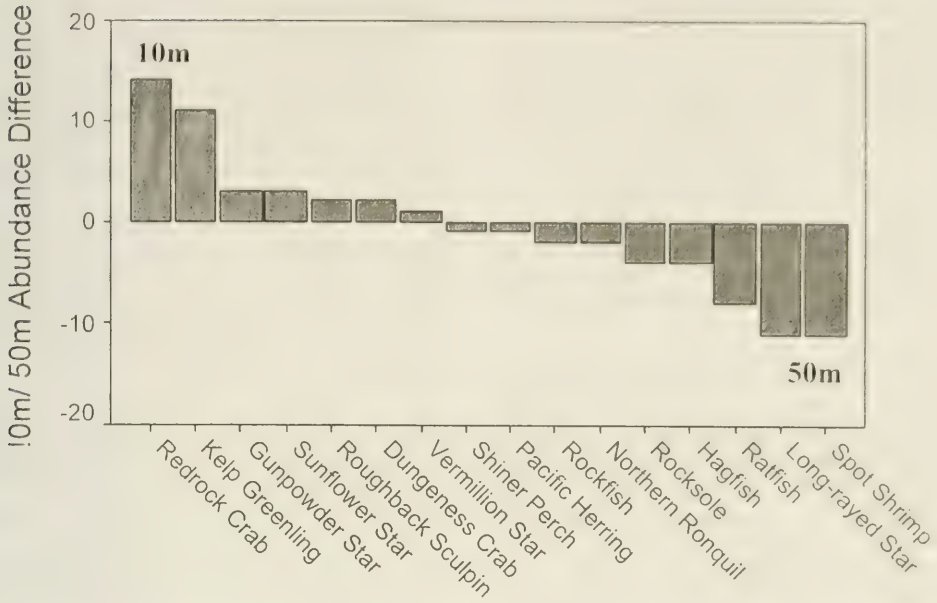

FIGURE 2. Relational abundance of scavenger species at carrion anchored at 10 m and 50 m depth (number of individuals at 10 m – number of individuals at 50 m depth), Barkley Sound. Positive values show greater occurrence at 10 m depth. Negative values show greater occurrence at 50 m depth.

benthic habitats (Lalli and Parsons 2001) and may reflect predator avoidance or reduction in competition. The agonistic encounters observed among crabs and fish indicate that carrion represents significant local energy enrichment to the benthic community (Stockton and DeLaca 1982).

Spotted Hagfish were the major scavengers at 50 m and were largely nocturnal, consistent with the findings of Fernholm (1974). These fish play an important role in the turnover and cycling of nutrients (Lesser et al. 1996; Collins et al. 1999). We observed a much higher rate of tissue loss at the 50 m site where hagfish

were prevalent. Since hagfish are dependent on food falls, specialized adaptations to minimize competition are present. Knotting is considered to be an important feeding behavior in which the hagfish attaches to prey with tooth plates and passes a knot from the caudal region anterior towards the head allowing tissues to be ripped off (Collins et al. 1999). We also observed this behavior, but only on a single occasion. Rather, hagfish primarily used full body spinning to pull pieces of tissue from the carrion. Such full body rotation is also present in sharks feeding on large prey and may allow an increase in their effective gape (Helfman et al. 1997).

Hagfish produce copious amounts of slime when feeding, agitated or threatened (Strahan 1963; Tamburri and Barry 1999). There are probably diverse functions to this slime including burrowing, defense and competitive exclusion (Collins et al. 1999). Hagfish burrowed into the carcass up to ¾ of their total body length. While the mucus may facilitate entry into the carrion, the burrowing would also cover the gills and this would limit gas exchange of the hagfish. This suggests the potential for posterior cutaneous respiration. Lesser et al. (1996) noted that hagfish skin was well-vascularized and hagfish are therefore able to survive with plugged nostrils and no respiratory current across the gills. Slime produced by hagfish has high strength (Fudge et al. 2003) and can also obstruct mouthparts and gills of other species attempting to feed at food falls (Tamburri and Barry 1999; Collins et al. 1999). Our ROV observations are consistent with these suggestions. Two of the ratfish swimming in close proximity to the foraging hagfish quickly succumbed, presumably from loss of respiratory ability. The close proximity suggests high efficacy and rapid effects of the hagfish mucus in natural conditions even under high dilution effects. If these observations are representative, it suggests that hagfish may not only have a substantial competitive advantage over other fish species in these episodic carrion fallouts but also operate as predators through the lethal influences of mucus on other scavengers.

Vors, Liv S. and Philip L. Wilson. 2006. A New Record Size Wolf (*Canis lupus*) Group for Ontario. Canadian Field-Naturalist 120(3): 367–369.

This report documents a group of 19 Wolves (*Canis lupus*) in northwestern Ontario. This is the largest group observed since record keeping in the Moose Aerial Inventory commenced in 1995. This large group may be a response to a high Moose (*Alces alces*) population in the Red Lake area.

Key Words: Gray Wolf, *Canis lupus*, social organization, pack size, Moose, *Alces alces*, Ontario.

The close association between Gray Wolves (*Canis lupus*) and their ungulate prey greatly influences the ecology of this cursorial predator, which is capable of killing prey much larger than itself (Kolenosky and Standfield 1975). Pack size is believed to be influenced by numerous factors. Pack sizes do not necessarily differ among Wolf populations whose major prey species are different. For example, average sizes of Wolf packs mainly depredating on Moose (*Alces alces*) are not necessarily larger than those feeding on White-tailed Deer (*Odocoileus virginianus*), but Wolf packs tend to be largest where Wolves prey on the largest ungulates (Fuller et al. 2003). This note documents one large group of Wolves observed in Ontario, Canada.

Observation

A group of 19 wolves was observed on 15 February 2005 between 1300 and 1400 hours on a frozen lake west of the settlement of Red Lake, Ontario, at approximately 51°05N and 94°05W. Red Lake (51°04N, 93°47W) is a settlement located in the boreal forest of northwestern Ontario. This sighting took place during a transect flight to map areas of Woodland Caribou (*Rangifer tarandus caribou*) habitat activity. The aircraft, a De Havilland Turbo Beaver, was flying at a speed of 90 knots and an altitude of 400 feet when the group was observed. Ontario Ministry of Natural Resources (OMNR) pilot Carl Hansson, Trent University graduate student Liv Vors, Sir Sanford Fleming College Fish and Wildlife Technologist graduate Philip Wilson, and Red Lake OMNR employee Claire Quewezence observed and counted the Wolves.

The aircraft made several circles over the animals, which were loosely congregated near the western shore of the lake. The Wolves ran around the ice, evidently disturbed by the aircraft, but made no attempts to flee into the neighbouring forest. No kill was visible. The animals were counted and confirmed by all observers. After about two minutes of observation, the aircraft resumed its transect flight.

Discussion

We believe this group to be the largest on record for Ontario, and possibly all of Canada east of the Rocky

Mountains. Wolf pack records are kept in the Moose Aerial Inventory Database 1995–2006*. Before this sighting the largest pack on record was 13, and was sighted in WMU (Wildlife Management Unit) 15A in 1998. Reported average pack sizes in Ontario range from 3.8 (Bergerud et al. 1983) to 5.9 (Pimlott et al. 1969) to 6.0 (Forbes and Theberge 1996), with maximums of 7, 9 and 13, respectively. Our observation of 19 wolves is significantly higher than most packs reported in Canada (Table 1).

Gray Wolves found in the North American landscape represented in their northern Ontario range predominantly prey upon ungulates and Beaver (*Castor canadensis*) (Carbyn 1987; Gauthier and Theberge 1987). Large packs likely provide increased hunting efficiency when prey is scarce, or may alternatively be a response to abundant prey (Schmidt and Mech 1997). We suggest the large group we observed is a response to the latter. Since 1975, Moose populations in the Red Lake area have increased from a density of 0.059-0.209 animals/km^2 to 0.359-0.509 animals/km^2 (McKenney et al. 1998). Current Moose densities in the Red Lake area are lower than McKenney's estimates. Moose in the Red Lake WMU were estimated to be 0.265 animals/km^2 in 2004 (unpublished data, Ontario Ministry of Natural Resources, Bracebridge, Ontario). White-tailed Deer are also expanding their range northward, providing additional prey (Red Lake OMNR, personal communication). Wolf density is positively correlated with ungulate numbers (Fuller 1989; Messier 1994). Although Moose density has declined since 1998, the ungulate biomass may still be high enough to support a large Wolf population.

The relationship between pack size and prey size, however, is imperfectly understood. While food acquired per Wolf may be positively correlated with pack size (Nudds 1978), this relationship is not consistent. A review of prey use by Wolves in several geographic areas suggested a negative relationship between pack size and food acquisition (Schmidt and Mech 1997). In addition, prey size and pack size may not be closely linked. Mech (2000) observed a pack of 22-23 wolves in Minnesota, and this group preyed primarily on White-tailed Deer. Consequently, prey size and food acquisition are unlikely to be the only factors explaining the large group we observed. An additional caveat is the group we observed may have consisted of several packs that converged at the time of observation.

An additional point of interest was the colour of the wolves. All were dark brown or black, with the exception of one silvery-white individual. Most wolves in eastern Canada are gray, with black and white individuals constituting approximately four and less than one per cent of the population, respectively (Gipson et al. 2002).

Acknowledgments

The aerial surveys were funded by the Ontario Ministry of Natural Resources, The Wildlands League, The Wildlife Conservation Society, and The National Geographic Society. Many thanks to Brent Patterson for his comments on the manuscript.

A Tribute to Nicholas Stephen Novakowski 1925–2004

Joseph E. Bryant

447 Thessaly Circle, Ottawa, Ontario K1H 5W7 Canada

Bryant, Joseph E. 2006. A tribute to Nicholas Stephen Novakowski 1925–2004. Canadian Field-Naturalist: 120(3): 370–378.

Nicholas Stephen Novakowski was an enthusiastic and very knowledgeable wildlife and fisheries scientist. Although his list of published works is modest, he was well known and respected across Canada and in several international fora. He has been credited as "the person who saved the Wood Bison as a discrete subspecies" (W. E. Stevens, personal communication) and was highly engaged in the early years of the surveys and recovery of the Whooping Crane (Novakowski, 1965b, 1966). Following those early days at Fort Smith, North West Territories, Nick was transferred first to the Edmonton office of the Canadian Wildlife Service and then to CWS headquarters in Ottawa where he was appointed Staff Specialist, Mammalogy, and took on national and international responsibilities. He retired in 1983 but continued his strong support for endangered wildlife and their habitats until his death on 3 July 2004 in Ottawa. He is survived by his wife, Amy, and two sons, Kent, a professor of hydrogeology and environmental engineering at Queen's University and Erin Nicholas, a professor of geography and environmental studies at Memorial University.

Nick was born 28 November 1925 in Mundare, Alberta (about 70 km east of Edmonton), the second child and eldest son in a family of 10 children. His father owned a Chrysler dealership and garage and from an early age Nick learned about all things mechanical – a fact that would stand him in good stead in later years as a field biologist. He also developed an abiding loyalty to Chrysler products and, briefly, owned only one automobile that didn't bear that company's mark. Finding the alternate car highly unreliable, he soon returned to his original choice and did not waver again. In his younger years he was a superb athlete. He and his brothers Archie and Van were well known in central Alberta hockey circles as a high-scoring powerhouse. Nick, who was ambidextrous, could play either wing and was a sharp goal tender (Ken Novakowski, personal communication). Also in those early years he became an ardent angler and as often as possible visited members of his extended family who lived in towns north of Edmonton. One of his favourite spots was Siebert Lake. Just a couple of weeks before his death he very happily returned there with his sister, Sharon, and her husband to renew those earlier experiences – with considerable success. Time had not dulled his expertise.

Nick entered the University of Alberta in 1947 and in the following two summers worked on forest fire suppression crews based in Fort Smith, North West Territories. There he became acquainted with Bill Fuller, the resident mammalogist for the Canadian Wildlife Service. He graduated with a B.Sc. in Chemistry in 1950 and that summer returned north but this time he was hired by Northern Transportation Company Limited (NTCL) for summer work on the docks at the company's shipping base near Fort Smith. At that time NTCL gave hiring priority to young men who could enhance its baseball team and Nick "was a very good ball player" (W. A. Fuller, personal communication). Nick returned to the University of Alberta that autumn to begin a Master's program and went back to Fort Smith in the spring of 1951. That autumn Dr. Fuller was assigned to conduct research of Wolves in Wood Buffalo National Park (WBNP) and adjacent areas of the Mackenzie District and employed Nick as an assistant (see Fuller and Novakowski 1955). Nick also helped Fuller with his studies of Beaver and with the "autopsies of lone, crippled, bison we encountered from time to time" (W. A. Fuller, personal communication). It was the start of Nick's wildlife and fisheries career, and perhaps of equal importance, the start of the romance that led in June 1952 to his marriage to the love of his life, Amy Swartz, a Fort Smith school teacher from Saskatchewan.

Also in 1952, with Fuller's recommendation, Dr. D. S. Rawson accepted Nick for graduate studies in fisheries at the University of Saskatchewan. Over the next few years he worked very happily at his studies and as a fisheries biologist for the Government of Saskatchewan. Although only one published paper appears to have resulted from that work (Atton and Novakowski 1956), he authored or co-authored many in-house reports for the Saskatchewan government dealing with fisheries research and resource management. Amy Novakowski tells me that those were the happiest years of Nick's life – helped, no doubt, by the fact that Amy was able to accompany him on many of his extended field studies in northern Saskatchewan. The photograph accompanying this article was taken at that time.

After completing his M.Sc., (Novakowski 1955c*) Nick was hired by the Canadian Wildlife Service in 1956 and sent to Fort Smith. His mentor, Dr. Fuller, was transferred that year to Whitehorse, Yukon, and Nick dived immediately into Dr. Fuller's continuing studies of Beaver populations in the southwestern Northwest Territories, Wolves in Keewatin District (Flook and

FIGURE 1. Nick Novakowski, fisheries researcher, Lac des Iles, Saskatchewan, 1955.

Novakowski 1956*; see also Novakowski 2003) and Bison and Whooping Cranes in Wood Buffalo National Park.

In 1957, in the course of an aerial survey of Bison in WBNP, he discovered the presence of an isolated herd of Bison in the Nyarling River area in the northwest corner of the Park (Banfield and Novakowski 1960). Subsequent aerial and ground studies indicated that the herd might be Wood Bison genetically uncontaminated by the Prairie Bison that had been transferred to WBNP in the 1920s. In 1959, Nick was able to obtain specimens which were confirmed by the National Museum to be Wood Bison (Banfield and Novakowski 1960). In the following three years he arranged for over 70 live specimens to be trapped and tested for tuberculosis and brucellosis. Of those, 18 that were disease-free were moved in February 1963 to a large holding corral northwest of Fort Smith. Three calves arrived that spring and in early summer all of the animals were again tested for disease. All were clear. Nick had previously scouted out appropriate habitat north of Fort Providence, North West Territories (Novakowski, 1959d*), and 18 disease-free Wood Bison, including the new calves, were transported there in August 1963. That area, now known as the Mackenzie Bison Sanctuary, proved to be an excellent site and the small nucleus soon swelled. Subsequently other specimens were taken from the Nyarling River site, transferred to Elk Island National Park, and after a rigorous clean-up protocol, produced another disease-free herd of Wood Bison (Gates et al. 2001). Some of Nick's less well-known Bison research included "the first use of dental annuli to estimate the age of bison" (Christianson et al. 2005). The same authors also credit him with being the first to measure and to demonstrate the usefulness of other Bison dentition measurements in aging large samples.

In 1958, Nick was also in charge of stocking Pine Lake and a few smaller lakes in WBNP with Rainbow Trout. He established and operated a small hatchery for that purpose, putting his Saskatchewan fisheries experience to good purpose (Novakowski 1958c*, 1959c*).

In 1962, when anthrax struck the Bison population just outside WBNP, it was the first recognized instance in Canada of anthrax in wildlife and all concerned were faced with a very steep learning curve. Nick worked closely with a team of scientists from the Canadian Wildlife Service, the Health of Animals Branch of the federal Department of Agriculture, and medical personnel to bring it under control (Novakowski et al. 1963; Choquette et al. 1972).

Dr. Fuller had engaged the interest of a long-time trapper in the southern portion of WBNP, Solomon Lacaille, to help with Muskrat studies (Fuller 1951). Nick followed through and set up a multi-year study on Mr. Lacaille's trapline to study many aspects of beaver biology and ecology, leading to his Ph.D. from the University of Saskatchewan in 1965 (Novakowski 1965a*, 1967a, 1969a).

The nesting grounds of the Whooping Crane, long an international mystery, were discovered in 1954 in the northern portion of Wood Buffalo National Park. In the subsequent two years the site was monitored by Dr. W. A. Fuller. Nick took over those studies in 1956 and monitored the small breeding population for several years (Novakowski 1966, 1967d). He was also responsible for capturing an injured juvenile whooper in 1964 and for ensuring its safe conduct to the breeding facility of the United States Fish and Wildlife Service near Washington, D.C. (Novakowski 1965b, 1965e*). That bird, a male named "Canus" for its dual nationality, sired "over 180" (E. Kuyt, personal communication) Whooping Cranes over its long career. It died in January 2003. The mounted body was repatriated to Canada and is now installed at the Northern Life Museum in Fort Smith, N.W.T. (E. Kuyt, personal communication).

Nick's work on Wood Bison and Whooping Cranes introduced him to the burgeoning field of rare and endangered species. It was a field that would occupy much of his attention for the remainder of his life. The Canadian Wildlife Service moved Nick to a Staff role in Ottawa in 1966. J. Anthony Keith, who was Nick's immediate superior in the Canadian Wildlife Service for much of his time in Ottawa, reported that "Nick Novakowski was the founding voice in CWS headquarters for wide-scale collaborative action on endangered species, beginning in 1967 when he was Staff Specialist, Mammalogy. While his own earlier work on Whooping Cranes became the trademark federal endangered species project, there was a continuing debate amongst headquarter staff about how far CWS should get involved in endangered species work. Nick had to argue against those who saw it as a diversion of limited resources from urgent wildlife conservation issues. He worked with Ted Mosquin to produce the first set of scientific articles in Canada on endangered vertebrates (*The Canadian Field-Naturalist* 84(1) 1970), writing the article on mammals." [*See* Novakowski 1970b].

In 1973, Nick represented the Canadian Wildlife Service at the international negotiations in Washington of what became the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). While John Heppes joined CWS to establish the Canadian management authority for CITES, Nick chaired the scientific authority until he retired in 1983 (Burnett 1999, page 162).

Nick Novakowski and John Heppes worked well together. Their first task was to convince provincial governments that CITES would not interfere with provincial authority over wildlife resources. John dealt with the administrators and enforcement personnel while Nick met with the wildlife managers and scientists. "Nick showed an amazing understanding and ability in persuading all concerned to fully cooperate ..." (J. Heppes, personal communication). Canada ratified the Convention in early 1975. Every two years there was

a "Conference of the Parties" at which member nations negotiated changes. "It was at these Conferences that Nick really proved his worth. In his role as Scientific Advisor he was always able to present the Canadian viewpoint in a clear and concise manner. While usually a calm and collected person, Nick could at times be very forceful in getting the Canadian opinion across … he was respected by many international authorities who often sought his advice on biological status of endangered species and his assistance in presenting their positions." (J. Heppes, personal communication).

Eugene Lapointe, the first Secretary General of CITES, remembers Nick's contributions for their scientific rigour and said, "My recollection of Nick is that he played a key role at the CITES meeting held in Gabarone, Botswana in 1983. The international community had an opportunity to realize what real and credible science was all about, and that thanks to Nick. I always perceived him as one of the most candid scientists. He was highly respected by his peers from the CITES community" (E. Lapointe, personal communication).

I recall one meeting in Ottawa where Canadian Non-Government Organizations (NGOs) were presenting their concerns about an upcoming Conference of the Parties. Two delegates were particularly vociferous in their assault on a proposed Canadian position. Nick as usual was thoroughly prepared and met both scientific and emotional arguments with calm, well-reasoned, non-confrontational responses which won the day.

Nick was also front and centre in the discussions leading up to the establishment of the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). Ted Mosquin recalled that as he was preparing draft recommendations for an upcoming symposium on Canada's Threatened Species and Habitats in 1975 Nick suggested that he look into the UK model that had "a unique committee that addressed the matter of the status of endangered species in the UK. [Nick] came over to the CNF office to fill me in on how the UK system worked. The result was a draft recommendation … which led to almost immediate establishment of COSEWIC by agreement of CWS and provincial agencies via the Federal Provincial Wildlife Conference" (T. Mosquin, personal communication).

"Throughout Nick's work as a senior scientist in headquarters, he maintained a network of colleagues in provincial and territorial governments. Nick's credibility with these colleagues was vital in their governments' agreement in 1977 to the initiative that became the Committee on the Status of Endangered Wildlife in Canada (COSEWIC), with Nick elected as its first permanent secretary. During the first formative years of COSEWIC Nick did outstanding work helping to forge a new way of doing business, helping to bring federal, provincial, territorial and non-government agency people to agree on publicly-released status reports. Making public the facts about endangered species was what Nick had been calling for since 1967, believing that this would lead to remedial actions supported by the public. COSEWIC continued to grow in the spirit of Nick's early aspirations, and recently was established as a formal entity under the *Species at Risk Act*." (J. A. Keith, personal communication).

In addition to Nick's work as COSEWIC secretary, he maintained his avid interest in species biology. He wrote the original Wood Bison status report and contributed to others. He also chaired the Marine Mammal and Terrestrial Mammal subcommittee in 1980 and, when it split, he chaired the Terrestrial Mammal subcommittee from 1981 to 1984.

Dr. Novakowski was involved in a much broader scope of activities than this review can encompass but three items may help to round out the story. For a number of years in the 1960s and 1970s he was involved with the search for more humane traps for capturing furbearers. His field experience with trappers proved very useful. He thoroughly understood the trappers' needs (Novakowski 1958d*) and also the political pressure being created to do away with the leg-hold trap. In 1967 he gave a brief but cogent review of the problem to the Federal-Provincial Wildlife Conference (Novakowski 1967e) and continued to be involved with the resulting program to develop humane traps until his retirement. Another example of his varied work involved blocking the introduction by an Ontario fur rancher of several dozen Raccoon Dogs (*Nyctereutes procyanoides*) from Finland. When the news arrived on Nick's desk, he nearly blew a fuse! He was one of the very few people in Canada who had the knowledge to foresee a disastrous outcome if those animals were allowed to stay. He knew from the literature and from his many European colleagues that if the animals ever got loose the species could have devastating ecological effects. And he knew that no matter what precautions were taken, sooner or later some of them would get loose. He sought the assistance of Dr. Eric Broughton, a veterinarian with the CWS, to have Agriculture Canada deny the import permit. No dice – there was no basis for denial on environmental grounds. Nevertheless, based on knowledge of the ecology of the species, he convinced Canadian authorities that the animals posed an unacceptable threat to Canadian wildlife and obtained authorization to have all of the imports killed, the pelts processed by the Hudson's Bay Company and compensation made to the owner. But he didn't leave it there. Nick pursued the problem domestically and with the United States authorities resulting in a formal Canada–USA agreement to bar the future importation or Raccoon Dogs into either Canada or the USA (E. Broughton, personal communication). A third dimension of Nick's professional work involved teaching a variety of courses, including biology, terrestrial ecology, and wildlife management at University of Ottawa, the University of Guelph, and Sir Sandford Fleming College in Lindsay, Ontario.

After retiring from the Canadian Wildlife Service in 1983, Dr. Novakowski became active as a scientific

consultant and engaged in a wide range of projects. In some cases he worked independently. In most he served as a member of a consulting team. In one of his early projects, he worked with Ted Mosquin to consolidate and review many earlier reports on Caribou and fur-bearers in Pukaskwa National Park (Novakowski and Mosquin 1986a*, b*, c*, d*). Dr. Mosquin recently commented: "Nick provided the publications/reports, guidelines, policies, appendices, survey data, illustrations, etc. as well as some text. I basically organized and wrote the reports based on the material and discussions. He was the expert. We worked well together and I learned a lot! ... We sometimes sat for more than a few hours trying to figure out what needed to be said and how to best say it."

Several of Dr. Novakowski's post-retirement projects dealt with major Environmental Impact Assessments of such projects as the Military Low-Level Flying program in Labrador, uranium mining in northern Saskatchewan, the Rafferty-Alameda dams proposal in southern Saskatchewan, military base proposals in the arctic, and bison management in Wood Buffalo National Park. He became very knowledgeable about environmental impact assessments in Canada and contributed behind the scenes on a variety of policy issues. He also contributed to a review paper on the evolution of environmental impact assessments of watershed modification projects (Dirschl et al. 1992).

In 1982, a year before Nick retired from the Canadian Wildlife Service, Dr. Husain Sadar arrived at the Federal Environmental Assessment Review Office (FEARO). In a letter following Nick's death, Dr. Sadar wrote that one of his "major responsibilities was to organize teams of highly recognized, accomplished and credible independent experts and specialists to assist and advise [the independent review panels] for analyzing and addressing often complex scientific, technical and socio-economic issues ... Nick served as an independent expert for several panels [dealing with] some of the most difficult, controversial and complex mega project proposals ... the panels benefited immensely from Nick's unique experiences and expertise in wildlife management and habitat protection. Whether the issue was protection of caribou herds, moose, large carnivores, furbearers, waterfowl, seabirds, birds of prey, marine birds or deer, Nick's critical analysis, evaluation and resolution of all such issues was simply outstanding ... But the most important quality of Nick's wonderful character was his ability to interact and work with other professionals in a highly professional, civilized and friendly fashion. He truly was a real gentleman."

Dr. Herman Dirschl, with whom Dr. Novakowski collaborated on many contracts, recalled their joint efforts on some of those major projects and commented, *inter alia* that, "Nick could be very passionate in his views, particularly when political decisions seemed to often favour short term economic gains at the expense of the long term environmental health. However, he managed to always stay calm and collected in the face of such adversity. I admired him for this ability and will greatly miss him." Dr. Dirschl also recalled their work "on an assessment of priority habitat sites throughout Canada to be considered for protection by the Canadian Wildlife Service in concordance with the Federal Government's 'Green Plan' goals. Nick took on the responsibility for reviewing the site records for a total of 262 sites in all provinces and territories; designing a classification system and defining latitude/longitude centroids for each site."

Even Canada Post sought out Dr. Novakowski's advice in planning for a commemorative postage stamp featuring Beaver – the 150th anniversary of the original 3¢ Beaver stamp (Novakowski 1997*).

Nick the scientist was also Nick the practical environmentalist. Early in their stay in Ottawa he and his wife, Amy, bought 150 acres of forested land in nearby Lanark County. It was covered primarily with second growth hardwoods but also had a small plantation of Red Pine which Nick carefully nurtured. He became very interested in the "Model Forest" concept and was a very keen member of the "Eastern Ontario Certified Forest Owners."

I leave the closing words to his good friend, car pool partner and long-time professional colleague, Gerry Lee: "On a house visit one day, Nick invited me into his garage to see his latest pride and joy. There sat a beautiful cedar strip canoe, like a collector's piece of rare furniture, hand built by canoe builder Nick for one of his offspring. Apart from the odd comment previously about 'building a boat someday,' I had no inkling of his interest or talent in this area. So much for thinking you know someone! To sum up, Nick to me was the consummate good guy; respected professional, devoted family man, equally devoted environmentalist, polite, humble and honest. A good friend I'll never forget."

Acknowledgments

Nick's wife, Amy, was very supportive, provided copies of important papers, and authorized the use of the photograph used in this tribute. His brother, Ken, provided details of Nick's early family life. Several librarians were especially helpful in assembling the lists of Dr. Novakowski's publications and unpublished reports: Terri Fraser, Canadian Wildlife Service, Edmonton; Jean-François Bélanger, Environment Canada Library, Gatineau, Quebec; Carol Schurr, former librarian, and Rob Wallace, Fisheries Ecologist, Saskatchewan Resource Stewardship Branch, Saskatoon; Staff, Library and Archives Canada, Ottawa, and Keith Van Cleave, Librarian, Northern Prairie Wildlife Research Centre, Jamestown, North Dakota. Many former colleagues of Dr. Novakowski provided assistance: I thank in particular Bill Fuller, Tony Keith and Gerry Lee for their contributions and for their very helpful comments on an earlier draft of this paper. Additional thanks are due

Eric Broughton, Herman Dirschl, Don Flook, Andy Hamilton, John Heppes, Ernie Kuyt, Eugene Lapointe, Alan Loughrey, Ted Mosquin, Doug Pollock, Dick Russell, Husain Sadar, Ward Stevens, John Tener and Don Thomas. I also thank my wife, Mary Bryant, for her constant support and assistance.

Bibliography

This bibliography is divided into published and unpublished sections. While many of Nick's reports were never published, their listing helps to demonstrate the breadth of his professional activities. Most reports prepared for the Federal Environmental Assessment and Review Office (FEARO) are not listed, in line with the terms of the contracts under which they were produced. Listings are chronological irrespective of whether Nick was the sole author, lead author or junior author.

ZOOLOGY

The Birder's Companion

By Stephen Moss. 2007. Firefly Books Ltd., 66 Leek Crescent, Richmond Hill, Ontario L4B 1H1 Canada. 208 pages. U.S. $16.95

This book is an entry in the "everything you ever wanted to know about birds" category. Each of its ten chapters deals with some aspect of birds – where do birds live? How do birds eat? Where do birds go? And, yes, each chapter does consist of a series of questions and answers – over 450 in all – together with side-bars giving what can best be described as "gee-whiz" facts relevant to the chapter's topic, all in roughly 20 pages or less each.

Maybe a disclaimer is appropriate at this point – this kind of book turns me off. With that out of the way, Moss has done a creditable job in amassing a formidable series of facts and presenting them in a simple, colloquial style. In the introduction the author quotes a friend who suggests the book would appeal to "intelligent, inquiring eleven-year-old boys", and while the author clearly hopes to appeal to a much wider audience, he makes no apology for his approach.

In spite of its disarming level of simplicity, the book is very well thought-out, up-to-date, and quite accurate. I imagine I could find an error or two in all this mass of data if I tried hard enough, but the fact remains that I didn't. He even – glory be – gives the correct origin for the word "jizz" , with no inanities about "general impression of size and shape" usually parroted as the origin nowadays. My main quarrel with the text is the inevitably high level of simplification, which constantly left me feeling "yes, but..." Some of the author's generalizations seemed very broad, and I wondered how he arrived at them; but again the ones I could check seemed within reasonable bounds.

The author is British, and this can sometimes be a problem when writing for a North American audience. However, in this case the book is very carefully tailored to North America. One minor area where it could be misleading was in references to "buzzards", the European name for *Buteo* hawks, but also a term colloquially used in parts of North America for vultures. Not only are we not told what buzzards are, but there are no buzzards in the index. One reference, to them being eaten by the European Eagle Owl [also not in the index]; was a particularly poor choice, given that Great Horned Owls will attack Red-tailed Hawks similarly.

The weaknesses in the index are by no means confined to these two examples. It seems to place most of its emphasis on the material in the side-bars, and the text as a whole is far less well covered. This is particularly unfortunate because for me, at least, this is not a book to read from cover to cover, but is best dipped into from time to time, as some topic of interest arises. For such uses, a thorough index is very important.

There is a one-page bibliography, although again some transatlantic emphasis creeps in, as many of the references are British – it's hard to see the relevance of the UK breeding bird atlas – but more importantly they may be hard to find on this continent. The line illustrations are not one of the strengths of the book.

My carping aside, this book would appeal to novice birders or anyone with a mild interest in birds. Its appeal to more experienced birders is perhaps more limited, but it's an easy read, best taken in small doses, and you'll probably find some things you didn't know. And I seriously think it could be a very good gift for intelligent, inquiring eleven-year-olds.

Birds of the Dominican Republic and Haiti

By Steven Latta, Christopher Rimmer, Allan Keith, James Wiley, Herbert Raffaele, Kent McFarland, Eladio Fernandez. Princeton Field Guides, Princeton University Press. 2006. 258 pages. U.S. $35.

Hispaniola, the second largest island in the Caribbean, has a wealth of habitats and of birds, making it an emerging destination for birdwatchers. It also has immense development challenges, most acutely felt in Haiti, the poorest country in the western hemisphere. These development challenges translate into conservation challenges, putting Hispaniola's ecological richness at peril. This book, the latest in several Caribbean guides issued by Princeton, is thus doubly important, both as an aid to identifying the island's birds, but also as a valuable conservation tool which maps the current avian diversity of the island and communicates the value and beauty of the island's birds to local populations.

The book will be instantly familiar to anyone who has seen any of Princeton's earlier Caribbean guides, such as *A guide to the birds of the West Indies* by Raffaele et al. Indeed, some of the plates have been taken from that earlier guide. The book follows a standard formal, with front pieces speaking to the topography and habitats of the island (from the highest mountains in the Caribbean, at 3098 m, to the lowest lake, at 44 m below sea level), endemic species (31) and subspecies (50), avian conservation, and the island's ornithological history. This is followed by detailed species accounts with information on similar species, vocalizations, habitat preferences, status, nesting, and global range, as well as a "comments" section containing interesting anecdotes such as the place of the bird in local culture. Each species account is accompanied by an up-to-date, detailed map of the bird's distribution on the island. This information is complemented by 56 colour plates, most of which group up to 10 similar species however, pride of place is given to the island's endemic species and one endemic family (Palmchat), which merit larger portraits. The book closes with descriptions of 14 birding sites and a checklist.

The species accounts are accurate and provide sufficient information to identify most species. Particular attention is paid to the resident species most likely to be of interest to visitors, thus ensuring that one is indeed able to safely differentiate Long-billed and Narrow-billed Todys, the vireos, and other potentially confusing groups. Canadian readers will find the discussion of Bicknell's Thrush of interest as Hispaniola is the chief wintering ground of this enigmatic breeding species. In general, the treatment of migrants is better than in many other regional guides; while you might want to lug around a good North American guide for some of the shorebirds and basic plumaged warblers, the level of detail in the plates is impressive and will usually suffice (e.g, if you look closely you can see the differently marked tertials in the illustrations of Long-billed and Short-billed dowitchers). In general the plates have the rather washed out and sombre tones of the earlier Princeton guides, and in some of the portraits the feathers have a rather messy look, not unlike old museum specimens, but this is a stylistic quibble; on the whole the plates are very good. While the decision to illustrate all 306 species which have been recorded on the island has considerable merit, having three illustrations of a bird which has only occurred once (Swainson's Hawk) would seem an inappropriate use of always scarce space.

The authors largely follow standard taxonomy, but have jumped the gun on American Ornithologists' Union orthodoxy by accepting recently proposed revisions, such as treating the Hispaniolan Nightjar as distinct from the Cuban Nightjar, both traditionally combined as one species known as Greater Antillean Nightjar (confusingly, the latter name is used in the similar species account under Least Pauraque, one of relatively few editorial errors in the book). Similarly, the authors have abolished the names of two endemics, Green-tailed Ground-Warbler and White-winged Warbler which have now morphed into Green-tailed Ground-Tanager and Hispaniolan Highland-Tanager, respectively. Some other incipient splits and lumps are suggested in the text, reflecting the fact that yet more work needs to be done on the island. Likewise, the species accounts indicate that several species have been added to the island's avifauna in the last decade, suggesting a recent increase in coverage and the possibility that the island's bird list will grow: the local occurrence of several pelagic species in particular seems to be poorly known.

Who should buy this book? Someone with a general interest in Caribbean birds may be better served by *A guide to the Birds of the West Indies* by Raffaele et al., which covers Hispaniola along with the rest of the islands. But anyone planning to travel to this beautiful island, or with a keen interest in Caribbean ornithology, would be well advised to acquire a copy; the range maps and site guides alone are worth the price if you are planning a self-guided visit (but better still, go with one of the organizations cited in the book). Finally, and most importantly, there should be a copy in every school and public library on the island: one hopes that Spanish and French versions are in the works.

Atlas of Bird Migration – Tracing the Great Journeys of the World's Birds

Edited by J. Elphick. 2007. Firefly Books Ltd., 66 Leek Crescent, Richmond Hill, Ontario L4B 1H1 Canada. 176 pages. $35.

Firefly Books has come out with another decent book. They've claimed the target audience to be, "bird enthusiasts, naturalists and the inquiring reader" and those who "wish to comprehend the perilous voyages that constitute one of the great wonders of the natural world." The book is written to be consumable by people in grade school and perhaps almost fully understood by those as young as 12 or 14 years of age; it will be an enjoyable, and not too taxing to read for adults who have a passing interest in the topic. Serious birders will want to go elsewhere for more in-depth descriptions of the topics.

The book starts out with 15 two-to-four page chapters on the biology and environmental conditions of migration, including timing, flight styles, genetics and weather. For the most part, these are well-illustrated

synopses of the topics. The subsequent chapters are organized into sections covering major geographic areas (e.g, Eurasia, southern hemisphere, oceans), with two to eighteen chapters per section. Each chapter covers an order or family of birds, using one to four species as examples. There is a map as well as a calendar showing migration and breeding times for most of the illustrated birds.

Although the book is worldwide in scope, it is dominated by a British point of view; after the typical migration pattern of a species is noted, the accidental occurrences in Britain (but nowhere else) are described (if such has occurred). The global perspective is worthwhile, though only a small fraction of the planet's migratory birds can be described.

There are a few mistakes scattered throughout the book; these include classifying the Great Horned Owl as an irruptive species, labelling Lake Winnipeg and its neighbours as the Great Lakes and describing the furcula as a pit (it is the wishbone). Many folks will gloss over these, but the more demanding reader will catch them; mistakes are never desirable, but most of these are relatively minor.

In addition to covering distance migrants, the book pays some attention to altitudinal migrants. When appropriate, the authors have included conservation messages on topics such as introduced species, habitat loss and the implications of commercial fisheries on birds.

Overall, this wouldn't be a book I'd give one of my serious birder friends as a gift, but it would do nicely for the beginner who is just migrating into the hobby.

RANDY LAUFF

St. Francis Xavier University, Antigonish, Nova Scotia

Handbook of the Birds of the World Volume II – Old World Flycatchers to Old World Warblers

By Josep del Hoyo, Andrew Elliott and David A. Christie (Editors). 2006. Lynx Edicions, Montseny, 8, 08193 Bellaterra, Barcelona, Spain. 800 pages. 199 Euros Cloth.

Handbook of the Birds of the World. Volume II covers eight families containing 733 species each with its own account and distribution map. The first of these is the Old World Flycatchers which, with the prejudices of youth, conjure up visions of Little Brown Jobs (LBJs). LBJs are the birders bane; small obscure birds that are difficult to see and identify. My first encounter with an Old World Flycatcher was the Spotted Flycatcher. This is an LBJ where "spotted' is an overstatement. They are only faint marks on the breast. This is a sweeping and somewhat unfair assessment as more than 40 percent of Old World Flycatchers are colourful. Indeed, the 22 members of *Cyorrus* are as colourful as North American Bluebirds.

In the next family, the Batises are small and largely black-and-white, whereas Wattle-eyes are somewhat more colourful with some orange and yellow. Many of the Monarch-flycatchers are a smart blue, but others are black and brown or black-and-white. However, the members of the small family of Paradise Flycatchers are among the most spectacular of the world's birds. One of my life's highlights was seeing the display of the black-and-white morph of the Madagascar Paradise Flycatcher. Similar and equally impressive species live in Africa and India. Kinglets and Firecrests is a family that is split between the old and new worlds. They are woodland sprites that can be surprisingly "cute" despite an initial dull impression. Gnatcatchers is a family of small, grey, long-tailed birds and is the only one in this volume that is confined to the new world. To my mind their counterparts are the Prinias of Africa and Asia.

Cisticolas and allies are a bit of a nightmare. Most of them are true LBJs being streaky or dull brown. Knowing their songs and distribution helps. Even the easier to recognise birds like the Common Jery of Madagascar and the long-billed Tailor Bird of Asia can be a problem. They are so active that critical characteristics can be hard to see. Whenever you think you have seen all the relevant characteristics, after the bird has flown, you often discover there was something critical you missed!

The 270 species of Old World Warblers in the Sylviidae (with 14 species confined to the antique island of Madagascar) are mostly LBJs. They are some of the most difficult birds to identify in the field. This nightmare is composed of several genera with hyphenated names like bush-warbler, reed-warbler, leaf-warbler and swamp-warbler. While there are discernable differences between, say, leaf- and swamp-warblers within each group there are many look-alike species which vary only by minuscule differences in eye-stripe or bill length. I spent every lunch hour for two weeks beside a Willow Warbler's nest so that I could identify this species with confidence. This meant I could better see the subtle difference between Willow Warblers and Chiffchafs [greener versus browner, etc.]. Unfortunately these birds are variable. The reader need only compare the photo of a pale, greyish Willow Warbler on page 551 with the brownish-yellow one on page 514 to understand this difficulty. It gets even worse with birds like the newly split Booted Warbler [*Hippolais caligata*] and Syke's Warbler [*H. rama*] Syke's Warbler winters all over India whereas *H. caligata* is found only on the eastern coast between the Ganges and Pondicherry. So the two species overlap in the east and are almost identical. As they do not sing in winter it will take a DNA test to separate them!

So how did *Handbook of the Birds of the World. Volume II* fare in dealing with birds that are not as magnificent as albatross or wildly coloured like parrots? It actually does remarkably well. Once again we have a well-organized and researched volume that adds to the

growing status of this project. As each new volume is produced it adds to the benchmark status of the existing volumes as a primary source of information on the world's birds. The format has remained stable for the last several volumes, which makes it easy to use and compare. The photos are top rate despite the small and obscure nature of these species. I know how difficult it is to get **any** photographs of such little and active sprites, let alone artistic ones of birds singing or displaying. *Handbook of the Birds of the World* has now reached biblical reference status.

ROY JOHN

2193 Emard Crescent, Beacon Hill North, Ottawa, Ontario K1J 6K5 Canada

Conservation of the Black-tailed Prairie Dog: Saving North America's Western Grasslands

Edited by John Hoogland. 2006. Island Press, Washington, DC. 350 pages paperback U.S. $35.

It is amazing how the conservation of an animal as interesting and entertaining as the Black-tailed Prairie Dog can be so controversial. But controversial it has been in the last few decades as environmental interests have woken up to the fact that the campaign of Prairie Dog poisoning and habitat loss has resulted in a range contraction to less than 2% of the historical geographic distribution. To this day many ranchers actively dislike Prairie Dogs for their competition with livestock for rangeland resources. In contrast, some conservation practitioners think that enough other species rely on the habitat created on Prairie Dog colonies that Prairie Dogs should be considered a keystone species. In my own practice as a biologist at Grasslands National Park, Saskatchewan, I have frequently been taken aback by how polarized the opinions on Prairie Dogs can be between individuals and groups that often share many similar core values.

The book, *Conservation of the Black-tailed Prairie Dog: Saving North America's Western Grasslands* is the brain child of Dr. John Hoogland who has researched the behaviour of Prairie Dogs at Wind Cave National Park in South Dakota since the mid-1970s. Dr. Hoogland felt that there was a need to summarize the extensive scientific literature on the Black-tailed Prairie Dog in a non-technical format designed to highlight the information's relevance to conservation. To accomplish this Dr. Hoogland engaged 30 other specialists and challenged them to draw out the lessons for conservation from their areas of specialty. These lessons are explored through 18 chapters on topics such as natural history, social behaviour, competition with livestock, keystone species, human attitudes, and how to establish new colonies of Prairie Dogs. The chapter authors are all respected specialists and do an excellent job of relating their topic area to the central theme of the book: the conservation of Black-tail Prairie Dogs.

The only significant criticism I have is that Dr. Hoogland repeatedly states in Chapter 2 that Black-tailed Prairie Dogs do not hibernate. This is odd because published studies have shown that Black-tailed Prairie Dogs use facultative torpor (Lehmer et al. 2001). In fact, in southwestern Saskatchewan, at the northern edge of their distribution, Black-tailed Prairie Dogs spend as much as 95 days a year in winter torpor bouts lasting 7.6 to 13.6 days with minimum core body temperatures ranging from 7.1 to 11.6°C (Gummer 2005). Clearly, this behaviour deserved to be recognized and discussed as to how it might relate to efforts to conserve this species. Despite this small failing, I fully recommend this book to anyone interested in the conservation of this fascinating social rodent or who wants to become better informed on conservation issues on the Great Plains.

Migrating Raptors of the World: Their Ecology and Conservation

By Keith L. Bildstein. Cornell University Press, Sage House, 512 East State Street, Ithaca, New York 14850 USA. 332 pages. U.S.$35.00 Cloth.

Raptors and bird migration both hold great fascination throughout the world, so the combination of the two topics makes for an irresistible book. Bildstein is a foremost world authority. Based at Hawk Mountain, the world's first site dedicated to the conservation of hawks and the watching of their migration, he is the Sarkis Acopian Director of Conservation Science. Bildstein tells us that "a bad day at Hawk Mountain Sanctuary is better than a good day anywhere else."

His wide knowledge derives in part from his travels to each of the world's main hawk-watching sites. Figure 1 displays the five major hawk pathways throughout the world and Figure 7 shows the 12 locations where 100 000 or more raptors pass by. In addition to studies at Hawk Mountain, banding of thousands of raptors has occurred at Cedar Grove, Wisconsin; Cape May, New Jersey; Hawk Ridge on Lake Superior, Minnesota; the Goshute Mountains, Nevada; the Manzano Mountains, New Mexico, and Golden Gate Observatory, California. Notable Old World banding sites are Chokpak Pass, Kazakhistan, and Elat, Israel. Switching

to birds counted overhead, 851 600 Honey Buzzards flew over Elat in the spring of 1985; there the spring flights are much larger than in fall. Elsewhere large numbers are counted in the fall: an average of 730 000 at Corpus Christi, Texas; 5 200 000 near Cardel in the state of Veracruz, Mexico; 1 950 000 at Keköldi Indigenous Reserve, Costa Rica, and 380 000 over the Strait of Gibraltar at the western end of the Mediterranean. In Veracruz, sometimes dubbed the "river of raptors," 2 677 355 Turkey Vultures were counted in 2003, 2 389 323 Broad-winged Hawks in 2002 and 1 197 850 Swainson's Hawks in 2003, including 782 653 in one day, 17 October that year.

Recent advances in technology have provided a big boost to raptor migration studies. Application of satellite radios to 117 Ospreys and 51 Golden Eagles added immeasurably to our understanding of the speed and variability of migration. Nine satellite-tracked Honey Buzzards averaged 270 km/day across the Sahara Desert, with brief stopovers suggesting that most fasted during at least this leg of their trip south. Since raptors often reduce energy requirements by soaring in thermals, Bildstein has included a map and three diagrams of the major deflection/updraft corridors. Raptors are able to orient and navigate simultaneously (setting a direction and then achieving it), using internal magnetic cues, visible landmarks, the sun by day, the stars for the few species that migrate by night. Despite a great deal of research, their navigational prowess still exceeds human comprehension. In at least nine species, including harriers, accipiters and two falcons, the juveniles precede the adults in southward migration, yet come spring the adults often head north first. In the Osprey and a few other species, juveniles spend an extra year in the tropical wintering habitat before returning north at two years of age.

A positive feature is that a number of hawk watching stations, including Hawk Mountain, were founded as conservation measures. Incensed by the carnage along the Kittatinny Ridge at Hawk Mountain, Rosalie Edge purchased the property and hired Maurice Broun to patrol it and count the raptors. Rachel Carson, in *Silent Spring* in 1962, used the 25-year Hawk Mountain counts, especially of declining Bald Eagles, to support her arguments concerning the impact of organochlorine pesticides, especially DDT, on the reproductive success of birds of prey.

Bildstein's final chapter is perhaps the strongest. It explains the widespread effects of bounties, not completely eliminated in Pennsylvania until 1969. From 1917 to 1952, Alaska territory paid bounties on 128 000 Bald Eagles. Today, the main threats to raptors are habitat loss and environmental contaminants, an example being a painkiller, diclofenac, fed to cattle in India, that has led to population declines of over 90 per cent for three species of vulture that eat dead cows.

My only criticisms are small ones. Because owls are also raptors, the absence of any mention of their nomadic movements, cyclical irruptions and migrations is somewhat contrary to the title of this book that is restricted to diurnal raptors. Readers of the main text might believe that DDT has long been banned everywhere, but in fact it is still being used in tropical countries to combat malaria and yellow fever. Only in the Glossary does Bildstein inform his readers that DDT is "still used by public health organizations to control malarial mosquitoes."

The writing is clear. Each chapter (I have only touched on a few highlights) ends with a synthesis and summary of the main points. This book is a treasure. It belongs in every high school and college library and in the library of every raptor enthusiast.

C. STUART HOUSTON

863 University Drive, Saskatoon, Saskatchewan S7N 0J8 Canada

Land Snails of British Columbia

By Robert G. Forsyth. 2004. Royal British Columbia Museum, Victoria, British Columbia, Canada. 188 pages. $35. Paper.

The study of snails has certain advantages for a naturalist. For one thing, unlike birds or butterflies, they move slowly enough to be identified! However, anyone who has ever tried to identify snails will know that there is a dearth of readily accessible information out there to help with the task. This is a lack that Robert Forsyth has set out to remedy with his guidebook, providing help with the identification of 92 species of land snails and slugs found in British Columbia. This book is similar in layout and format to other recent guidebooks from the Royal British Columbia Museum, a handy 5.5" × 8.5" soft cover book, easy to slip into a backpack or daysack.

Each taxon is provided with a "species account" that consists of a description of the animal, its distribution, and its natural history (basically its habitat preferences). Each account also includes information on the etymology of the animal's name, some remarks, usually dealing with taxonomic issues or species with which it may be confused, and references. The species are arranged in taxonomic order. These accounts form the bulk of the book (128 pages). Most taxa are illustrated by line drawings or black-and-white photographs. For the planispiral snails, the images generally include the upper (apical) surface, lower (umbilical) surface, and apertural view. For the conispiral snails, the images generally consist of an apertural view and a distal view. There are also 33 colour images, of which 23 are of slugs. These colour images are generally much crisper and more useful than the black and white photos. Forsyth includes some brief discussion of eleven other taxa that he considers of doubtful occurrence in British Colum-

bia or that he judges to have equivocal taxonomic status. These are often species that were perhaps only recorded from one locality or for which the record was made many decades ago and has not been confirmed or supported by subsequent observations.

These species accounts highlight some interesting points about the land molluscs of British Columbia, as they are known at present. Of the species discussed, about one third (24) are slugs. Of these, more than half of them (13) are introduced. Many of these slug species are described as being common in gardens, which perhaps suggests that eagle-eyed gardeners may be responsible for drawing attention to them. Forsyth notes that many of these exotic species are significant agricultural pests, in contrast to members of the native fauna, which are not. He points out (page 19) that most may have been accidental introductions, brought in on plants or associated soil. Most of the snail species, in contrast, are native (53) with less than a quarter (15) identified as introduced. This striking pattern raises the question as to whether it is a consequence of the method of introduction (that is, on horticultural or agricultural plants) or simply a lower level of investigation of the mollusc fauna outside urban and intensively farmed areas. Despite its focus on British Columbia, many native species described by Forsyth have wider distributions. Some are found in other areas in the Pacific Northwest, from Oregon to Alaska. Others are more widespread and some occur east of the continental divide in other areas of western North America. Despite its focus on British Columbia, therefore, this book has wider applicability in western Canada.

The remainder of the book offers useful supplemental information. An extensive introduction (19 pages) describes the biology of the animals, including, for the snails, some discussion of shell characteristics, which are important for species identification. There is also a checklist of the species described in the volume, and two dichotomous keys, one for snails and one for slugs, to help narrow down the selection to genus. Ten other keys are interspersed among the species accounts and focus on genera, such as *Vallonia*, *Vertigo*, and *Arion*, in which there are more than a couple of species. All the snails described are dextral coiling species, as are most land snails. Following the species accounts, there is a lengthy (14 pages) reference list, a glossary of terms, and a species index.

I obtained this book primarily to help with the identification of mollusc shell remains recovered from fine-fraction analysis of sediment samples from archaeological sites and other postglacial depositional contexts. In these situations, the soft parts of the animals are not preserved and only the shells remain. Hence, identifications rely primarily on the morphology and structure of the shells. So I was particularly interested in the shell descriptions. In this regard, the book has been very helpful although I have noticed some limitations. My main complaint is that the line drawings are not reproduced well. This is a significant problem. On many drawings, the lines are faint and details of shell surface features and ornamentation are extremely difficult to discern. Moreover, Forsyth only provides one shell measure for each taxon. For the planispiral molluscs, he provides the width of shells, but not the spire height. For the conispiral molluscs, he provides the height of the shells, but not the width. The complementary measures can be approximated from the drawings, but it would have been useful to have them included in the text. The width/spire height ratio is an easily acquired descriptive character that helps discriminate different taxa.

Two additional sets of information would have made this book even more helpful. First, I thought each species could have been illustrated by a "dot map" showing the localities in British Columbia where it has been collected or observed. I imagine that the dots would have been very sparse for many species! Nevertheless, such maps could highlight areas that may well repay survey and collecting effort. Second, it would have been useful to have a list of the accession numbers for the specimens that were studied to compile this volume. This is important so that in future scholars could re-examine the specimens to confirm and refine the taxonomy or acquire additional measurements and images. Because the Royal British Columbia Museum is the publisher, I assume that it may be the institution housing these collections. However, this information (that is, the institutional repository and accession numbers) could have easily been included, for example, in the species checklist, making such detective work unnecessary.

Compiling this volume obviously involved a formidable amount of painstaking work and study. I heartily commend Forsyth's commitment to a neglected but rewarding faunal group. This book is a fine introduction to these animals and deserves to be on all western Canadian naturalists' bookshelves. Anyone who pays attention to the information in this volume will never look at a snail on a rockery or a slug on a cabbage leaf in quite the same way again!

ALWYNNE B. BEAUDOIN

Royal Alberta Museum, Edmonton, Alberta T5N 0M6 Canada

Songbird Journeys: Four Seasons in the Lives of Migratory Birds

By Miyoko Chu. 2006. Walker & Company, 104 Fifth Avenue, New York, New York 10011 USA. 312 pages. U.S. $23. Cloth.

This is a welcome, attractive, and highly recommended book. Each chapter is preceded by a well-chosen quotation, often an appropriate full-page poem.

Miyoko Chu has combined the best of investigative journalism with a passionate account of bird migration that holds the reader's attention. Four chapters deal with spring migration and two with fall migration. She also must deal with where these migrating birds summer and winter, so five chapters deal with these intervening seasons. Not only does she tell of the latest research into bird migration, but she interviews at length some of the leading authorities. Thus, we read fascinating stories about exceptional people who are studying interesting birds. I will mention a few highlights.

Her opening chapter deals with a long-unsolved question: do large numbers of birds make the seemingly impossible long-distance flight over the Gulf of Mexico, as George Lowery fervently believed, or was this a preposterous fiction of people's imaginations, as George Williams posited? Lowery began by studies through a telescope, and admitted that trans-Gulf migration was "fraught with enigmas and strained one's credulity." Williams accused Lowery of jumping from minute observations to sweeping conclusions, of extrapolating from the 12 birds he had seen through the telescope to claim a migration of 21 million birds. Sid Gauthreaux, when 17 years old in Louisiana, inveigled his way into one of the first weather radar stations and persuaded the meteorologists to let him look at the fuzzy dots that he thought must be movements of birds. He then persuaded Lowery to accept him as a graduate student, embarking on a master's thesis and then a doctoral dissertation that proved to doubtful ornithologists everywhere that radar was a superb modality for studying many aspects of migration. In so doing, he proved beyond doubt that Lowery was correct.

Frank Moore's group at Johnsons Bayou, Louisiana, studied weights and condition of migrants as they first reached landfall, after crossing the Gulf. Almost half the birds arrived with their fat reserves totally depleted.

Richard Graber, at Urbana, Illinois, was an incredibly early pioneer, four full decades ahead of the pack, in placing tiny radio transmitters on small birds. His friend, Bill Cochran, made him a number of tiny, 3 g transmitters, which he glued to the backs of thrushes that weighed about 30 g each. He tuned his receiver to the appropriate frequency and then followed the signals by truck, and once by aeroplane for 400 miles in eight hours. Cochran then took over the study and with special equipment he logged 150 000 miles by truck to follow individual birds for a total of 30 000 miles. He followed one Peregrine Falcon from Wisconsin to Tampico, Mexico, a Sharp-shinned Hawk from Cedar Grove, Wisconsin, to Huntsville, Alabama, and a Common Nighthawk from Illinois to South Carolina.

Another hero is a bird, a Yellow Warbler, nicknamed "Wally," that carried band 1750-17109, and returned for nine years in a row, to sing near the Long Point Bird Observatory in Ontario. At Hubbard Brook in New Hampshire, where Richard Holmes and his colleagues have studied birds since 1969, bird numbers have declined by about sixty percent. There, Black-throated Blue Warblers produce more young in years when caterpillars are common and in La Niña years.

When Olin Sewall Pettingill was a boy in Maine, his mother showed him a Bobolink nest. But they faced hazards. About 720 000 Bobolinks were shipped as game from one place in South Carolina in 1912 alone. In Argentina, Pettingill learned in 1978, Bobolinks were now being shot as pests for eating rice crops. It is not surprising that the number of breeding bobolinks has dropped by 75 percent in 25 years.

A new branch of science, studying the calls of nocturnal migrants to recognize individual species, was pioneered particularly by Bill Evans in 1985, who produced a cassette tape of the night calls of the thrushes. His compilations were joined by those of Michael O'Brien in 1991. Four years later they had "nailed down" the final two species that had eluded them, the night calls of Canada and Wilson's Warblers. By 2001, they produced the landmark guide that identified the flight calls of 211 species of migrating landbirds in eastern North America. Collaboration with researchers and software programmers at the Cornell Laboratory of Ornithology allowed analysis of different bird species from their individual characteristics. There are now thirty rooftop stations monitoring nocturnal migration with these new methods. Although Chu fails to list the Evans/O'Brien CD in her references, it became available in 2002 and can be ordered through http: oldbird.org.

Only in 1995 was Bicknell's Thrush recognized by the American Ornithologists' Union as a separate species from the similar Gray-cheeked Thrush. Chris Rimmer studied this thrush, one of the rarest migratory birds in North America, in its breeding habitat among the stunted firs near the top of Mount Mansfield in Vermont. But where did they winter? Rimmer's crew found them in the Sierra de Bahoruco in the Dominican Republic and, miracle of miracles, in 1995 captured in a mistnet one of the banded birds they had tagged in Vermont the previous summer – and then recaptured the same bird again in Vermont during the next two summers!

The reader is also given detailed directions to North American birding migration hotspots, in both spring and fall, and mid-winter hotspots in Yucatan, Belize, Costa Rica, and Panama. She provides instructions for amateurs to help contribute to knowledge, by partici-

pating in Nest Record Card programs and Project FeederWatch.

Chu concludes by calling attention to the many hazards facing bird populations, such as loss of habitat, increasing parasitism by cowbirds, deaths from striking windows, communication towers, pesticides, carbon dioxide emissions, and acid rain. Twenty-nine species have declined by more than fifty percent in the last 40 years. Despite these losses, the arrival of songbirds every spring remains a cause for celebration.

BOTANY

Wildflowers of the Rocky Mountains

By G. Scotter and H. Flygare. Whitecap Books, 351 Lynn Avenue, North Vancouver, British Columbia V7J 2C4 Canada. 255 pages. $ 29.95 Paper.

Plants of Alberta

By F. Rover and R. Dickinson. 2007. Lone Pine Publishing. 10145 – 81 Avenue, Edmonton, Alberta T6E 1W9 Canada. 527 pages. $ 29.95 Paper.

It is most interesting that these two books have been published within such a short space of time. They were of immediate interest to me as I visit family in Alberta and usually manage a trip or two to the Rockies or the prairies. While they cover very different areas they include many of the same species. Furthermore, the authors have taken significantly different approaches.

Wildflowers of the Rocky Mountains [*Wildflowers*] contains 350 species of selected plants in six sections by flower colour [white, yellow and cream, green, pink, red, orange, and brown, purple and blue.] Each page depicts typically two species, all with a description, a photograph and a range map. The authors say they have chosen the most common species (typically the pretty species) likely to be encountered during visits to the Rockies, plus a few rarities. The area covered is the Rocky Mountain zone from northern British Columbia to New Mexico. This is a complete revision and expansion of a 1986 guide, that covered 228 species. The authors state that over the years they have learned to use non-technical language. They have been successful in applying this talent and has produced a very readable book.

I have a few problems with *Wildflowers*. I have a different view on the choice of colours. For example, I consider Mountain Sorrel to be reddish-brown not pink as the authors contend. Similarly, I think of Flame-coloured Lousewort (*Pedicularis flammea*) as red, but the authors have placed this plant in the cream section (because the flowers have a cream base). To further add to my confusion this plant is called Oeder's Lousewort (*P. oederi*) but *P. flammea* is given as the synonym. (However a web search of *P. oederi* showed images of cream-only flowers, while an image search for *P. flammae* showed cream-based flowers with significant amounts of red on the tips. A search for synonyms of *P. oederi* did not include *P. flammae*.) The alternative names are not included in the index. Many of the English, and some of the scientific names are not the ones I am used to. As an example, this book's Four-part Dwarf Gentian or Felwort is called Alpine Gentian in other texts.

The range maps are coloured in for the entire state or province regardless of how widespread the plant is. So Bear Grass is shown as occurring in Alberta, whereas it can only be found in the vicinity of Waterton Lakes National Park. This greatly reduces the usefulness of these maps.

I thought the approach used by *Wildflowers* – arranging the species by flower colour – was useful only for beginners. After a couple of years most people know the major families, like vetch, violet, saxifrage and so forth and I thought this is the way people progressed. Recently I was told that women prefer books organized by flower colour and I found my wife agreed.

The photographs are very good and will be useful in identifying blooms in the field. The descriptions in *Wildflowers* are written in prose, often in a poetic style that makes for pleasant reading. There is an excellent introduction on the eco-zones and a wonderfully clear glossary.

The second book is *Plants of Alberta* (*Plants*) which covers over 1500 native plants that can be found in Alberta. It is arranged by family and includes aquatic plants, grasses, ferns and trees (so not just the pretty flowers). Certainly I prefer the *Plants* method of arranging by families so I can reference all the orchids, violets, louseworts, etc. together. It too has a description, a photograph and a range map also shown two to a page. There is a short introduction and a decent glossary.

Plants' descriptions are cryptic and scientific. Compare "While other saxifrages may dress in flowers of white or yellow, Purple Mountain Saxifrage is garbed with flowers of the richest rose-purple to royal purple" (in *Wildflowers*) with the terse "Flowers: Purple (occasionally pinkish or white.)" (in *Plants*)

The photos in *Plants* average about twice the size of those in *Wildflowers* – a considerable benefit. This is achieved by having no margins, giving 20% extra space. Also the headers giving the plant names and family are 60% smaller [but less artistic!]. As the text is shorter the text size is bigger – great advantage for older eyes. The larger script comes at the loss of poetic text to terse notes. So despite the book's slightly smaller pager size (10%), by the creative use of space the publishers have created a more appealing looking book.

The range maps cover Alberta and show the area within the province where you can see the plant. This is useful because it shows over 35% of Alberta's species are confined to the southern border with British Columbia and the United States. As the maps are small (1 × 2 cm) they require some interpretation. I photographed a Striped Coralroot in Bow Valley Provincial Park, so I verified that the range map showed this plant at this location. It does, but it required careful examination and analysis due to the size. The other distributions are equally valid.

There is also a key arranged by leaf structure and flower colour. This uses thumbnail (¾") photos of the families. So *Violas* appear in the white, yellow and purple sections. Is this enough to satisfy the ladies?

Despite my clear preference for *Plants* as a book, I would say that both of these books are good guides. The photographs are excellent and the text, while very different in style, gives solid information. Your choice should be dictated by your intentions or location. Alternatively, and this I suggest is the best idea, you could buy both as both, are good value for money.

MISCELLANEAOUS

Pilgrimage to Vallombrosa: From Vermont to Italy in the Footsteps of George Perkins Marsh

By John Elder. 2006. University of Virginia Press, Charlottesville, Virginia, USA. xv + 282 pages. U.S. $29.95 Cloth.

This book is a story of pilgrimage, of memory, of hope. It's a beautiful book, a book of life, of family, of nature and culture. John Elder, a professor of English at Vermont's Middlebury College, invites the reader on a pilgrimage. It is a story of connections; from the second and third growth sugar bush hills of Vermont to the centuries-old, culturally prestigious forests of Vallombrosa in the Tuscany hills; from the sugar bush to the olive grove; from Robert Frost to Dante.

Vermont-born George Perkins Marsh was Abraham Lincoln's diplomat to the new Kingdom of Italy from 1861 until his death in 1882. Considered to be America's first environmentalist, Marsh was the author of the celebrated *Man and Nature* (1864). Inspired by his study of the rise and fall of Mediterranean cultures and his extensive experience of the region, Marsh's manifesto focused on environmental decline as central to the collapse of these once powerful cultures. Marsh was the first to describe and document the drastic, long-term impact of deforestation on civilization. His *Man and Nature* stirred the American imagination as America itself experienced the wave of deforestation flowing from east to west across the American landscape.

A sabbatical year permitted Elder and his wife to set out on a pilgrimage across France and Italy. Elder's purpose was to pursue the footsteps of Marsh who died in Vallombrosa in 1882. A pilgrimage usually has a set route, but novelty and surprise are to be expected. A pilgrimage on foot always becomes a pilgrimage of the heart and of the mind. Elder skillfully invites the reader on a pilgrimage of ideas, one that examines our place in nature.

Elder divides his pilgrimage into three landscapes, each connected to Marsh's vision of conservation. First is the journey to and within Tuscany, the crucible of Marsh's thinking in the city of Florence, the surrounding hill towns and the celebrated forests of Vallombrosa. Second, is the literary landscape where Elder situates Marsh within the lineage of William Wordsworth, Matsuo Bashô and Robert Frost. The final section returns to Vermont, to Marsh's native Woodstock, the sugar bush of the Elder family, and to the Vermont-wide conservation initiatives.

Those who set out on a pilgrimage usually have a destination in mind. But that is often the only sure thing about a pilgrimage. It's what happens in between that counts and that often surprises. Nothing is hard and fast for Elder, nothing black-or-white. He writes skillfully of what he terms the "middle landscape," that ecotone where wilderness and civilization meet. It is upon that middle ground that Elder chooses to focus, weaving the theme of "stewardship" throughout his work.

The term "stewardship" has fallen on hard times in certain intellectual circles. Its anthropocentric connotations are too aristocratic, too old-fashioned for some. Not so for Elder, who calls for a mutuality of human history and natural history. He calls for preservation of not only biodiversity but also human values and community, a place where technology and religious faith both have their own special role to play. For Elder, the environmental crisis is ultimately a crisis of culture, a crisis of the human soul, a crisis of the human heart. Stewardship, brought into proper dialogue with contemporary ecological, feminist, religious and social justice thought, can engender the cultural and moral resources necessary to address the environmental needs of our time.

Elder's attempt to re-frame the discussion is welcome. Too often has environmental conversation fractured into dualistic dichotomies, into opposing camps of nature and culture. We need both voices to forge a social ecology, where ecosystems are not considered in the absence of culture and vice-versa. It's that middle ground that provides the vital connection between

remote regions of wilderness and the places were we live, work and play.

We must thank Elder for eschewing sectarian language. His goal takes much more effort. It seeks a common ground that does not reduce to the lowest common denominator. The built environment, the cultivated environment, the wilderness environment; they all have a voice that needs to be heard. Elder speaks in the tradition of Aldo Leopold, René Dubos and Wendell Berry, voices that seek a dialogue between culture and the wild. For all three, the steward is the facilitator of such a needed task. The steward lives in that "boundary zone where the wilderness ethic may engage with recent developments of environmental history, and where the ideal of preservation transcending our narrow utilitarianism may engage with the tradition of stewardship." (page 218)

This is marvellous meditation. It's no wonder, since Elder's trade and tackle are words and stories. He weaves a story, a meditation, a contemplation that opens up our mind and heart to new possibilities for our relationship to forests, to those wild and wonderful places. It is a story of people tending the olive groves under the warm Tuscany sun, and of his own family's stewarding of the sugar maple groves of their Vermont home. Landscape and culture provide the nexus of discussion. Forgetting one or the other dehumanizes us and sets the stage for either pillage or misanthropism.

In this era of apocalyptic predictions, environmental and social haemorrhaging, a widening gap between culture and nature, between rich and poor, urban and rural, Elder sets out a path of reconciliation, a path that seeks the common good. It's a path laced with community, dialogue, a sense of the sacred, good work, justice, stewardship, care and respect. These virtues don't come easily.

A final word to Elder: "I have come to believe that without the stories that integrate the face of nature with the drama of our human lives, society will not have the power to restrain our appetite and respect the larger balance of nature." (page 67) If you accept this conclusion, read this book. It will draw you into a world of memory and elegance. If you don't agree with Elder, read this book anyway. The full, inclusive fare offered by Elder will call you into a respectful dialogue.

JOHN MCCARTHY

Ecology Project, Ignatius Jesuit Centre of Guelph, P.O. Box 1238, Guelph, Ontario N1H 6N6 Canada

Where to Watch Birds – World Cities

By Paul Milne. 2007. Yale University Press P.O. Box 209040, New Haven, Connecticut 06520-9040 USA. 496 pages. U.S. 28.00 Paper.

This type of book is a reviewer's dream. Before you open it you know the author, Paul Milne, must make choices and these will not be the same as your choices. This means you know you will have the opportunity to criticize. So how well do his choices match those I would have made? First he has included only one Canadian city, Toronto. It is Canada's largest city but it is not the capital nor the best for the naturalist. One out of the 60 cities covered in the book seems a little thin for second largest country in the world [even if we rank 36th for population]. Putting my obvious bias aside, I noted that other key cities are missing. Oslo, with its great royal park, and Kiev, a city of wonderful chestnut trees, are two evident examples. Indeed 60% of the cities are in Europe and Asia; a disproportionate number for these two continents over North and South America and Australia.

Accepting the author's choices, how useful is this book? First this book covers more than the city itself. When I visit Victoria, British Columbia, I get up at dawn and walk from my downtown hotel through Beacon Hill park to the coast. I return before breakfast and then go to my meeting. These two hour jaunts have netted me some very interesting birds [e.g. Ancient Murrelet]. These activities were all within the downtown core of Victoria and did not involve any travel. The author includes in his version of "city" many areas that require significant travel – you will need a car. The equivalent of me driving to Goldstream Park, 17 kilometres from downtown Victoria, and more. Indeed some sites are over 100 km away (distances are given in the measurement used in the country; e.g., they are in miles in the U.S. and kilometres in Canada.)

Accepting the author's broad boundaries how useful is this book? I would say very useful indeed. I have birded in almost half of the cities mentioned [generally without a car] and have visited many of the sites he describes. He has an introductory section that explains the city in birder's terms and has a good section on transportation. Where there is a good public transportation to suitable birding locations (e.g., London, Moscow) the author provides enough information to get the traveller started. The site descriptions are clear and accurate and I wish I had owned this book years ago. There are locator maps where they are appropriate. There is a list of birds typically seen at each location. This worked well for all places and I verified with my notes that I too had seen a similar list of species.

I can quibble on some minor points. For example, under Johannesburg he includes Suikerbosrand [upland species – about 70 km from Johannesburg] but omits the nearby Pilansburg – perhaps the best park to visit [lowland species – about 100+ km from Johannesburg]. His information on travel omits to say it would be almost suicidal for a tourist to drive in Mumbai. Taxis are cheap and you can get a car and driver, sympathetic to your needs, from the Bombay Natural His-

tory Society for reasonable cost. If you take a photo booth shot of yourself plus a glue stick to Austria, you can get a multi-day pass to Vienna's excellent public transit; a most economical way to travel.

All in all this is a great and useful book. My next trips are to Halifax and then Anchorage, but neither of these is included by the author. However, I look forward to using it on my next trip to one of the cities in this book, which will likely be Moscow. I would encourage Paul Milne to travel more in North and South America. Then I can hope he plans a second volume to cover some of the cities he has missed.

ROY JOHN

2193 Emard Crescent, Beacon Hill North, Ottawa, Ontario K1J 6K5 Canada

Marshes: The Disappearing Edens

By W. Burt. 2007. Yale University Press, P.O. Box 209040 New Haven, Connecticut 06520-9040 USA. 192 pages. U.S. 35.00 Cloth.

William Burt has a very deserved reputation. His photographs are amazing. As a naturalist who also takes photos I have some idea of the skill and the patience needed to get a good shot. Burt goes beyond good. Not only are the photos amazing in their quality, but he specialises in birds that are typically difficult to see! Take Black Rail as an example. I spent several hours at night wading in a swamp with an ardent group of seekers before I had my first glimpse of a Black Rail. It ran over my foot. It took another hour to actually get my binoculars [and flashlight] on one of the cute but elusive beasts. The idea of a photograph never entered my head. I do have some slides of other rail species I took mostly by good luck. They are nice, but they are not artistic and they all have little flaws. Burt's photos are technically crisp and clear. They are also artistic; the kind you would frame and hang on the wall.

In addition to birds, the author has also included a number of pictures of marsh vegetation and some of the more picturesque flowers. Actually this book is over 50% photographs.

Once you have finished drooling over the illustrations you could read the text. The author describes his visits to wetlands throughout North America. Starting with his home base in Connecticut river marshes he travels to Maryland (Elliot Island), Manitoba (Sewall Lake), Saskatchewan (Crane Lake), Oregon (Malheur) and California (Klamath). He also takes us on a trip through wetlands in Texas, Louisiana, Florida and Virginia. At each site he describes the value that each place brings and some of the issues it now faces.

Burt make an emotional, almost poetic appeal for marshes. He describes his favourite haunts along the east coast of the United States with such verve that I realised, somewhat for the first, that I too had experienced the same feelings. I tend to look at life more clinically, but Burt is more passionate and has shown that I have similar emotions to him below the surface.

I believe you should learn something new every day. I began to learn as soon as I started to read. For the first time I properly understand the issue with *Phragmites*. The ones I see are more likely the aggressive – and therefore dangerous – European plant and not the look-alike native version. Alien invaders are a key threat and *Phragmites* and loosestrife lead that charge.

His description of the work of the photographers Walter Finley and Herman Bohlman in the 1800s is enlightening on the persistence and dedication of these pioneers plus their resounding contribution to conservation.

This a lovely book and would make a wonderful present for both naturalists and non-naturalists. The beautiful writing style and powerful messages might even convert some folks to be conservationists.

Minutes of the 127th Annual Business Meeting of The Ottawa Field-Naturalists' Club 10 January 2006

Place and time: Canadian Museum of Nature, Ottawa, Ontario, 7:30 p.m.
Chairperson: Mike Murphy, President
Attendance: Forty-two persons attended the meeting.

Attendees spent the first half-hour reviewing the minutes of the previous meeting, the Treasurer's report and the Report of Council. The meeting was called to order at 7:40 p.m. with some opening remarks from the President.

1. Minutes of the Previous Meeting

Under Report of the Nominating Committee/Committee Chairs: The Chair of the Education and Publicity Committee should be corrected to read Gillian Marston not John Cameron.

It was moved by Gillian Marston seconded by Fenja Brodo that the minutes be accepted.

(Motion Carried)

2. Business Arising from the Minutes

There was no business arising from the Minutes.

3. Communications Relating to the Annual Business Meeting

There were no communications relating to the Annual Business Meeting.

4. Treasurer's Report

Frank Pope reviewed the financial report for the year ending 30 September 2005, noting that the Club's net assets had increased by approximately $86,350. This was due in large part to a bequest from the estate of Mildred Groh of $62,250. There was an amendment to the Report.

Moved by Frank Pope and seconded by Diane Lepage that the Financial Report be accepted as amended.

(Motion Carried)

5. Committee Reports

Mike Murphy introduced each of the Committee reports and a representative of the appropriate Committee and asked for questions and comments. He thanked the committee chairs and committee members for their work over the previous year.

Moved by David Hobden seconded by Gillian Marston, that the reports be accepted with suggested amendments.

(Motion Carried)

6. Nomination of the Auditor

Moved by Frank Pope, seconded by Bill Cody, that Janet Gehr continue as Auditor for another year.

(Motion Carried)

7. Report of the Nominating Committee

President	Mike Murphy
Vice President	Ken Allison
Secretary	Susan Laurie-Bourque
Treasurer	Frank Pope
Past President	Gary McNulty
Business Manager	Bill Cody
Editor, CFN	Francis Cook
Editor, T&L	Karen McLachlan Hamilton

Committee Chairs

Birds	Chris Traynor
Computers	Dan Millar
Conservation	Stan Rosenbaum
E&P	Gillian Marston
E&L	Fenja Brodo
Finance	Ann MacKenzie
FWG	David Hobden
Macoun rep.	Diane Kitching
Membership	Henry Steger
Publications	Ron Bedford
ON Rep	Eleanor Zurbrigg

Members at large
Susan Howell
Julia Cipriani
Justin Peter

Chairs not on Council

Awards	Ernie Brodo
Macoun	Rob Lee
Nominations	Fenja Brodo

Retiring from the council: Kathy Conlan, Louise Schwartz, Dave Smythe

New on the council: Ken Allison, Julia Cipriani, Susan Howell, Ann MacKenzie, Dan Millar and Justin Peter.

Moved by Fenja Brodo, seconded by Frank Pope, that the slate of nominations for the 2006 Council be accepted.

(Motion Carried)

8. New Business

There was no new business.

9. Presentation of Awards for the 2005 OFNC Photo Contest

There was a presentation of the awards to the winners of the 2005 OFNC Photo Contest by Suzanne Deschene and Gillian Marston. The grand prize winner received a digital camera and photo printer.

Amphibians:	Ruth Allison
Birds:	Lois Naggs
Insects and spiders:	Christine Hanrahan
Mammals and vegetation:	Jim Robertson
Scenery:	Stephen Darbyshire
Honorable mention –	
Birds and vegetation:	Gwen Williams
Grand prize winner:	Dave Sankster

The Education and Publicity committee was already planning the next photo contest, tentatively titled "The Tale of the Trail". Details to be published in *Trail & Landscape*.

The presentation of the awards was followed by a slide show of the contest entries. This was viewed with admiration and enjoyment by the members in attendance.

10. Adjournment

Moved by Henry Steger/Ron Bedford that the meeting be adjourned at 9:35 pm.

(Motion Carried)

SUSAN LAURIE-BOURQUE
Recording Secretary

The Ottawa Field-Naturalists' Club Committee Reports for 2005

Awards Committee

At the club's Annual Soirée, on 30 April 2005 at St. Basil's Church in Ottawa, awards were once again given to members, and two non-members, who distinguished themselves by accomplishments in the field of natural history and conservation, or by extraordinary activity within the club. There isn't always a winner for every potential award, and this year, once again, the Anne Hanes Natural History Award was not given. On the other hand, a new award was approved by Council and awarded for the first time this year: the Mary Stuart Education Award. This new award has been established for members, non-members or organizations in recognition of outstanding achievements in the field of natural history education in the Ottawa Region. The new Education Award was appropriately named in honour of Mary Stuart, who was so passionately interested in establishing a new generation of young naturalists. The winners of the 2004 Awards were:

HONORARY MEMBER:

Charles D. Bird – a long-time member of the OFNC and one of Canada's most outstanding naturalists in the fields of cryptogamic botany and entomology. He has been an associate editor of *The Canadian Field-Naturalist* for over 25 years.

MEMBER OF THE YEAR:

Marilyn Ward – for her efforts in handling the club phone, helping to make sure lecture and excursion events are successful, and keeping the Fletcher Wildlife Garden spic and span.

GEORGE MCGEE SERVICE AWARD:

Martha Camfield – for her many years of service with the Macoun Field Club both at meetings and in the field, and for her botanical work on the Leitrim wetlands.

MARY STUART EDUCATION AWARD:

Andrea Howard – for her extraordinary, innovative work in teaching natural history at the Eastern Ontario Biodiversity Museum in Kemptville and her "Museum in a Suitcase" school programs.

CONSERVATION AWARD – MEMBER:

Ghislaine Rozon – for her extraordinary efforts in trying to save the Larose Forest from destruction by developers.

CONSERVATION AWARD – NON-MEMBER:

Barbara Barr – for attending municipal and regional meetings and hearings regularly, mostly representing the Greenspace Alliance, gathering information, presenting briefs, and being a source of sage advice to policy makers on conservation issues.

The full text of the citations for each of these awards was read at the annual soirée and will be published in vol. 119, no. 4 of *The Canadian Field-Naturalist*.

IRWIN BRODO
Chair, Awards Committee

Birds Committee

The Birds Committee participated with the Club des Ornithologues de l'Outaouais in both the Christmas Bird Count and the Fall Bird Count. The compilation dinners for both events were very well attended. The committee again organized the Peregrine Falcon Watch at the nest site downtown. Donations to the watch in 2005 totalled $275. While both chicks fledged, one disappeared and its fate remains unknown. Sadly, the adult female, Horizon, was injured and subsequently euthanized at the request of the Ministry of Natural Resources. We continued to provide seasonal bird summaries for *Trail & Landscape*. Several members have also enhanced our committee's presence on the OFNC's web site. The 5th and final year of the Ontario Breeding Bird Atlas has been completed and a report summary has been prepared. The Bird Record Sub-committee met several times during the year to review rare bird records. The committee also provided several leaders for OFNC bird trips. The committee has also added a new bird feeder, provided by the National Capital Commission, near the new picnic shelter at the Mer Bleu. The 2005 seed-a-thon raised over $300 in pledges. We continue to operate the rare bird alert and Ottawa's bird status line which provides updates and information on both rare birds and regular report summaries.

CHRIS TRAYNOR
Chair, Birds Committee

Computer Management Committee

During 2005, the Club purchased two new computers, one for use by the Treasurer's Assistant; old equipment has been retired.

The Computer Management Committee reviewed how club volunteers manage key information holdings of the club, to ensure that club data are secure and accessible. Key files include the membership database, financial records, *Trail & Landscape* electronic archives, and *Canadian Field-Naturalist* files. The committee concluded that current data management practices are adequate.

There were no requests to the Computer Management Committee from other committees during the year for computer support, as they had expertise available in-house.

The club upgraded the capabilities of its web site considerably when it moved to a new service provider. These improvements are allowing the Web Master to continue to improve the content of our popular web site.

ELEANOR ZURBRIGG
Chair, Computer Management Committee

Conservation Committee

Alfred Bog

Frank Pope continues to chair the Alfred Bog Committee, while planning to hand over to a new person who has provisionally accepted this position.

Planning Reform

In follow-up to our 2004 brief and letters to Ontario Ministers, additional letters were sent on 19 May 2005, including a joint letter to the Premier and four Ministers, and individual covering letters to each. Frank Pope and Eleanor Zurbrigg presented our position on planning reform at the Ontario Nature/Federation of Ontario Naturalists regional meeting at Alfred College on 15 October. A meeting to discuss the issues with the ON/FON regional Board Member was set for 6 December.

South Gloucester (5309 Bank Street)

We sent notification by registered letter to both the Ministry of Natural Resources and R. W. Tomlinson, stating our continuing opposition to the granting of an aggregate extraction licence to which we had previously objected. We pointed out that R. W. Tomlinson's proposed mitigation measures for damage to significant plant species were dismissed in short work by Brunton Consulting Services in a second Peer Review specially ordered by the City. The issue was presently on hold pending hearings at the Ontario Municipal Board of appeals by the Greenspace Alliance and others.

Pesticide Use on Lawns and Gardens

Email letters were sent to the Mayor of Ottawa and Councillors, supporting a campaign that is trying to get the present (ineffective) policy of voluntary reduction in pesticide use replaced by a ban on the cosmetic use of pesticides. City Council rejected a ban, but the Mayor and some Councillors in favour of a ban stated that they would make this an election issue in 2006.

STAN ROSENBAUM
Chair, Conservation Committee

Education and Publicity Committee

KIOSKS, DISPLAYS AND OTHER EVENTS

The committee enhanced the material available for displays and kiosks by adding several light weight portable displays. Committee members participated with displays at the Ottawa-Carleton Elementary Teachers' Federation Publishers' Display, National Wildlife Week's Wildlife Festival, Environment Week Fair and Eco Fair at Friends of the Farm and the OFNC Soirée. Once again the OFNC participated in the Ottawa Science Fair sponsoring a prize for a project judged by Education and Publicity Committee member Kathy Conlan. The committee also arranged speakers for outside groups.

OFNC MEMBERSHIP DRIVE

The portable kiosks were used for approximately 10 outings for a successful spring club membership drive

DIGITAL LIBRARY

The committee has initiated the OFNC's 'digital photo library and catalogue' as a successor to the slide collection that the committee currently manages.

OFNC NATURE PHOTOGRAPHY CONTEST

The committee ran a members' photography contest to encourage discovery of nature and enhance the club's digital library. Over 200 entries were received and catalogued in the digital photo library.

BROCHURES

The committee continued to distribute the club brochure to area libraries and nature shops.

GILLIAN MARSTON
Chair, Education and Publicity Committee

Executive Committee

No report

Excursions and Lectures Committee

In 2005 this committee arranged 29 events, ten monthly meetings (including the Annual Business Meeting) plus the Soirée. The majority of our trips (twelve) were of general interest, two were devoted to plants, two to geology, four to mammals and invertebrates and nine were birding trips. The latter included our club's biannual bus trip to Pt. Pelee which was very well attended, and two winter birding trips in conjunction with the Kingston Field-Naturalists Club. There have been fewer birding trips the last five years because potential leaders were heavily involved with the Breeding Bird Atlas.

Something new in 2005 was a winter wildlife tracking excursion, on snowshoes, in the Gatineau. Also a first, club members were invited to join members of the Dragonfly Society of America, meeting in Amprior, on their scheduled field trips. Unfortunately a woodworking workshop had to be cancelled for lack of interest.

Our policy remains to arrange meeting places that are accessible by bus. The signed waiver forms allow us to track the popularity of events and help leaders to recognize participants.

Our monthly meetings cover a great diversity of subjects and most of our speakers are OFNC members.

FENJA BRODO
Chair, Excursions and Lectures Committee

Finance Committee

The Finance Committee met four times in 2005. Highlights include:

1. Increase in membership fees for the calendar year 2007

Fees had not been increased for at least four years, and some concerns were noted about gradually declining membership and operating deficits experienced over the previous few years. The committee recommended to Council that fees not be increased for calendar year 2006, but that the membership fees increase by at least $5 in 2007. These recommendations were approved by OFNC Council.

2. Meeting with the OFNC Auditor

The Treasurer, Frank Pope, and the Chair of the Finance Committee met with the OFNC Auditor, Janet Gehr. She advised that the financial health of the club was good compared to similar non-profit organizations and that we had ample reserves. She also advised that our computer hardware and software were adequate, as well as the club's record keeping and documentation. It was recommended that future financial statements include a note on potential liabilities related to the backlog of publication of the *Canadian Field-Naturalist*. The amount of deferred revenue which would cover a part of this financial commitment should also be noted. This recommendation was acted upon by the Treasurer.

3. Budget for 2005-06 Fiscal Year

A proposed budget for the OFNC and the *Canadian Field-Naturalist* for the period 1 October 2005 to 30 September 2006 was submitted to Council. A deficit of over $18,000 was forecast, and if realized would be a draw on the unrestricted reserve. Council approved this proposed budget.

4. Other Items

During the year the committee discussed the impact of changes in the federal government's Publication Assistance Program on mailing costs for *The Canadian Field-Naturalist* and *Trail & Landscape*, the increase to the audit fee from $1,000 to $2,000, a credit card for club business (not approved), the bequest from the estate of M. Groh, and reviewed the draft financial statements for 2004-05 before finalization.

LOUISE SCHWARTZ
Chair, Finance Committee

Fletcher Wildlife Garden Committee

The Garden completed another successful year with over 2000 volunteer hours contributed. We held or participated in a number of events. In February, it was the Great Backyard Bird Count and then an information table at the Pesticides Conference. April brought the Wildlife Festival with a display at Billings Bridge Shopping Centre, joint sponsorship of a seminar at the Canadian Museum of Nature and an event at our Centre for Annual Migratory Bird Day. Our annual plant sale in June raised over $2000. We also participated in a Central Experimental Farm Open House held in September.

Without a grant we were only able to have a part-time employee who worked on the interpretation program. Our preferred employee was unable to start immediately, so the program began later and ran through September.

Remodelling of the Backyard Garden continued. Some beds have been reshaped, a new entrance sign added and the patio re-laid. In 2006 most of the beds will contain only regional native flowers.

Our work on invasive plants continues. There is some success with buckthorn and garlic mustard, but swallow-wort continues to be a problem. All methods of removing it end up destroying everything else as well. We are also working on burdock, Canada thistle and amur maple which have become too common. Flowering rush and cat-tails are being removed from the pond. The pond itself is showing decreased biodiversity with very few insect larvae observed in 2005. The primary water source is agricultural run-off so this trend may be difficult to reverse.

In the spring we published a new general brochure in English, using a grant from TD Friends of the Environment Foundation and intend to seek another grant to publish the French version. Information sheets on burdock and garlic mustard were also produced. For the Central Experimental Farm Open House a bilingual miniguide was prepared to give an overview of what the Fletcher Wildlife Garden has to offer. This is now available to all visitors.

We have renewed the main entrance sign, enhanced the boundary sign system and the direction signs along the Bill Holland Trail. Other improvements include a small shed and gravel on heavily used parts of the trail system. During the winter there was considerable rabbit damage. We must expect this problem to continue until the local fox population recovers.

DAVID HOBDEN
Chair, Fletcher Wildlife Garden Committee

Macoun Club Committee

The committee met once during the year, with most of the planning being coordinated by telephone and e-mail. Committee members supervised or gave presentations at 18 indoor meetings (down from 44 last year) and led 14 field trips and one camping trip (roughly the same).

The much reduced number of meetings stems from the failure of a Senior (high-school-age) group to form this year, apparently for the first time in the Club's 57-year history. In part, this follows from weak participation over a period of years in the Intermediate (middle-school) group, which would normally feed into the Seniors. But it also appears to be a social phenomenon of a proliferation of competing activities, and ever more tightly scheduled lives.

Participation in the Junior group remains strong, although the same social pressures have become evident in the families of younger children, too. With no Senior members, the Macoun Field Club's annual publication (*The Little Bear*) had to be edited and produced by a committee member for the first time since 1988. The content, however, continues to be dominated by the children's work.

ROBERT E. LEE
Chair, Macoun Club Committee

Membership Committee

The distribution of memberships for 2005 is shown in the table on previous page, with the comparable numbers for 2004 in parentheses. These statistics do not include the 23 affiliate organizations which receive complimentary copies of *Trail & Landscape*.

During 2005, the club lost a long time member with the death of Eileen Evans, who joined the club in 1974 and served on Council as Corresponding Secretary from 1990 to 1996. Eileen was an important organizer and contributor to the social part of the monthly meetings at the Canadian Museum of Nature and the annual Soirée for many years.

DAVE SMYTHE
Chair, Membership Committee

Publications Committee

The Publications Committee met three times in 2005.

Only two issues of *The Canadian Field-Naturalist* were published in 2005: Volume 118, numbers two and three. These two issues contained a total of 336 pages; 32 articles; 15 notes; 41 book reviews; 71 new titles; 1 commemorative tribute; 14 pages of News and Comments; and 2 pages of miscellany. The journal fell further behind schedule largely because of some problems with the (relatively new) printer. These problems seem to have been solved, and the next four issues were near to being ready for production. The possibility of eventual electronic publication was considered at some length, and is continuing. For the present, the Abstracts of *CFN* papers will be posted on the OFNC website (to accompany the Tables of Contents which have been appearing there for some time). None of the Manning funds were drawn upon in 2005.

Volume 39 of *Trail & Landscape* was published in four issues containing a total of 200 pages having the usual excellent mix of articles.

RONALD E. BEDFORD
Chair, Publications Committee

Auditor's Report

To The Members of THE OTTAWA FIELD NATURALISTS' CLUB

I have audited the balance sheet of THE OTTAWA FIELD NATURALISTS' CLUB as at 30 September 2005, the statement of changes in net assets, and the statements of operations. These financial statements are the responsibility of the organization's management. My responsibility is to express an opinion on these statements based on my audit.

Except as explained in the following paragraph, I conducted my audit in accordance with Canadian generally accepted auditing standards. Those standards require that I plan and perform an audit to obtain reasonable assurance whether the financial statements are free of material misstatement. An audit includes examining evidence supporting the amounts and disclosures in the financial statements. An audit also includes assessing the accounting principles used and significant estimates made by management, as well as evaluating the overall financial statement presentation.

In common with many non-profit organizations, the Ottawa Field-Naturalists' Club derives some of its revenue from donations and fund raising activities. These revenues are not readily susceptible to complete audit verification, and accordingly, my verification was limited to accounting for the amounts reflected in the records of the organization.

In my opinion, except for the effect of the adjustments, if any, which I might have determined to be necessary had I been able to satisfy myself concerning the completeness of the revenues referred to in the preceding paragraph, these financial statements present fairly, in all material respects, the financial position of the OFNC as at September 30, 2005, and the results of its operations and changes in net assets for the year then ended in accordance with Canadian generally accepted accounting principles.

JANET M. GEHR
Chartered Accountant

North Gower, Ontario
3 January 2006

5. STATEMENT OF CHANGES IN NET ASSETS
   a) Unrestricted other revenue includes a bequest of $62,250 from the Estate of Mildred Groh.
   b) Manning OFNC expenses: Innis Point Bird Observatory $2,000, Peregrine Falcon Watch $649.
   c) Seedathon Expenses: birdseed for club feeders, $809.
   d) Louise de Kiriline-Lawrence Expenses: Contribution to the defence of the Larose Forest at a hearing of the Ontario Municipal Board.

6. PUBLICATION LIABILITY

An annual membership fee or subscription entitles the member/subscriber to four issues of *The Canadian Field-Naturalist* based on a calander year. As the year end of the club is September 30, the Club incurs a liability for publishing the fourth issue of each publication.

At this time, however, the publication of *The Canadian Field-Naturalist* is running late. At September 30, 2005, the club owes members/subscribers of 2005 issue number 4 of 2004 and three issues of 2005. Although most of the work preparing these publications is done by volunteers, the club must pay for printing and mailing. Based upon recent costs, it is estimated that the club has a liability of $68,000 for the outstanding issues. This amount will be reduced by page charges to the authors in the amount of 40% of the printing costs.

The Ottawa Field-Naturalists' Club Summary of Significant Accounting Policies

September 30, 2005

1. Nature of Business

The organization is non-profit and incorporated under the laws of Ontario (1884). The organization promotes the appreciation, preservation, and conservation of Canada's natural heritage. It encourages investigation and publishes the results of the research in all fields of natural history and diffuses information on these fields as widely as possible. It also supports and cooperates with other organizations engaging in preserving, maintaining or restoring environments of high quality for living things.

2. Financial Instruments

The organization's financial instruments consist of cash, accounts receivable, marketable securities, and accounts payable. Unless otherwise noted, it is the management's opinion that the organization is not exposed to significant interest, currency, or credit risks arising from these financial instruments. The fair value of these instruments approximate their carrying values, unless otherwise noted.

3. Capital Assets

Capital assets in excess of $4,000 cost are recorded as assets at cost and amortized on a straight-line basis. These assets have been fully amortized.

4. Statement of Changes in Financial Position

A statement of changes in financial position has not been provided as it would not provide additional meaningful information.

5. Foreign Currency

Transactions during the year in U.S. dollars have been converted in the accounts to Canadian dollars at the exchange rate effective at the date of the transaction. All monetary assets in U.S. dollars at year end have been converted to Canadian dollars at the rate effective on Sept. 30, 2005.

Gains or losses resulting therefrom are included in revenue or expenses.

Advice for Contributors to *The Canadian Field-Naturalist*

Content

The Canadian Field-Naturalist is a medium for the publication of scientific papers by amateur and professional naturalists or field biologists reporting observations and results of investigations in any field of natural history provided that they are original, significant, and relevant to Canada. All readers and other potential contributors are invited to submit for consideration their manuscripts meeting these criteria. The journal also publishes natural history news and comment items if judged by the Editor to be of interest to readers and subscribers, and book reviews. Please correspond with the Book Review Editor concerning suitability of manuscripts for this section. For further information consult: A Publication Policy for the Ottawa Field-Naturalists' Club, 1983. *The Canadian Field-Naturalist* 97(2): 231-234. Potential contributors who are neither members of *The Ottawa Field-Naturalists' Club* nor subscribers to *The Canadian Field-Naturalist* are encouraged to support the journal by becoming either members or subscribers.

Manuscripts

Please submit by post **to the Editor,** in either English or French, **three** complete manuscripts **written in the journal style.** Manuscripts may also be submitted (one copy) by e-mail. The research reported should be original. It is recommended that authors ask qualified persons to appraise the paper before it is submitted. All authors should have read and approved it. Institutional or contract approval for the publication of the data must have been obtained by the authors. Also authors are expected to have complied with all pertinent legislation regarding the study, disturbance, or collection of animals, plants or minerals. The place where voucher specimens have been deposited, and their catalogue numbers, should be given. Latitude and longitude should be included for all individual localities where collections or observations have been made.

Manuscripts should be printed on standard-size paper, **doublespaced throughout,** generous margins to allow for copy marking, and **each page numbered.** For Articles and Notes provide a bibliographic (citation) strip, an abstract, and a list of key words. Generally, words should not be abbreviated but use SI symbols for units of measure. The names of authors of scientific names may be omitted except in taxonomic manuscripts or other papers involving nomenclatural problems. "Standard" common names (with initial letters capitalized) should be used at least once for all species of higher animals and plants; all should also be identified by scientific name.

The names of journals in the Literature Cited should be written out in full. Unpublished reports and web documents should not be cited here but placed in a separate Documents Cited section. List the captions for figures numbered in arabic numerals and typed together on a separate page. Present the tables each titled, numbered consecutively in arabic numerals, and placed on a separate page. Mark in the margin of the text the places for the figures and tables.

Check recent issues (particularly Literature Cited) for journal format. Either "Canadian" or "American" spellings are acceptable in English but should be consistent within one manuscript. **The Oxford English Dictionary, Webster's New International Dictionary** and le **Grand Larousse Encyclopédique** are the authorities for spelling.

Illustrations

Photographs should have a glossy finish and show sharp contrasts. Electronic versions should be high resolution. Photographic reproduction of line drawings, **no larger than a standard page,** are preferable to large originals. Prepare line drawings with India ink on good quality paper and letter (don't type) descriptive matter. Write author's name, title of paper, and figure number on the lower left corner or on the back of each illustration.

Reviewing Policy

Manuscripts submitted to *The Canadian Field-Naturalist* are normally sent for evaluation to an Associate Editor (who reviews it or asks another qualified person to do so), and at least one other reviewer, who is a specialist in the field, chosen by the Editor. Authors are encouraged to suggest names of suitable referees. Reviewers are asked to give a general appraisal of the manuscript followed by specific comments and constructive recommendations. Almost all manuscripts accepted for publication have undergone revision—sometimes extensive revision and reappraisal. **The Editor makes the final decision** on whether a manuscript is acceptable for publication, and in so doing aims to maintain the scientific quality, content, overall high standards and consistency of style, of the joumal.

Special Charges — Please take note

Authors **must share in the cost of publication** by paying $90 for each page, plus $30 for each illustration (any size up to a full page), and up to $90 per page for tables (depending on size). Authors may also be charged for their changes in proofs. Reproduction of color photos is extremely expensive; price quotations may be obtained from the Editor.

Limited joumal funds are available to help offset publication charges to authors without grants or institutional support. Requests for financial assistance should be made to the Editor when the manuscript is submitted.

Reprints

An order form for the purchase of reprints or pdf will accompany the galley proofs sent to the authors. Invoices for publication costs will be sent when the submission is published.

Subscriptions and Membership
Subscription rates for individuals are $33 per calendar year. Libraries and other institutions may subscribe at the rate of $45 per year (volume). The Ottawa Field-Naturalists' Club annual membership fee of $33 (individual) $35 (family) $50 (sustaining) and $500 (life) includes a subscription to *The Canadian Field-Naturalist*. All foreign subscribers and members (including USA) must add an additional $5.00 to cover postage. The club regional journal, *Trail & Landscape*, covers the Ottawa District and Local Club events. It is mailed to Ottawa area members, and available to those outside Ottawa on request. It is available to Libraries at $33 per year. Subscriptions, applications for membership, notices of changes of address, and undeliverable copies should be mailed to: The Ottawa Field-Naturalists Club, P.O. Box 35069, Westgate P.O. Ottawa, Canada K1Z 1A2. Canada Post Publications Mail Agreement number 40012317. Return Postage Guaranteed. Date of this issue: October– December 2006 (January 2008).

A Reevaluation of Sexual Dimorphism in the Postcranium of the Chasmosaurine Ceratopsid *Chasmosaurus belli* (Dinosauria: Ornithischia)

JORDAN C. MALLON[1,3] and ROBERT B. HOLMES[2,4]

[1]Department of Earth Sciences, Carleton University, Ottawa, Ontario K1S 5B6 Canada; e-mail: jmallon@ucalgary.ca

Mallon, Jordan C., and Robert B. Holmes. 2006. A reevaluation of sexual dimorphism in the postcranium of the chasmosaurine ceratopsid *Chasmosaurus belli* (Dinosauria: Ornithischia). Canadian Field-Naturalist 120(4): 403–412.

The sexual dimorphism attributed to *Chasmosaurus belli* by Sternberg (1927) is revisited and reevaluated. A reexamination of the two specimens originally considered by Sternberg reveals that they are less complete than first suggested, with only a moderate amount of overlapping material between them. Only a few of the postcranial elements (humeri, sternal plates, and presacral vertebrae) show evidence of dimorphism, the significance of which is either doubtful or equivocal. Instead of representing sexual dimorphs, it is likely that the two specimens belong to separate species, *C. belli* and *C. russelli*, as evidenced by their distinct frill morphologies and by their stratigraphic segregation within the Dinosaur Park Formation of Alberta. These findings emphasize the need to remain sceptical about claims advocating sexual dimorphism in the fossil record in the absence of statistical significance or stratigraphic control.

Key Words: *Chasmosaurus*, Ceratopsia, Dinosaur Park Formation, sexual dimorphism, variation, Alberta.

Chasmosaurus are modest-sized (~1500 kg) ceratopsid dinosaurs known from the upper Campanian-aged beds (~75 Ma [million years ago]) of western North America. They are characterized by the possession of a premaxillary flange, recurved supraorbital horncores, and a broad parietosquamosal frill with a straplike posterior border (Forster et al. 1993). The type species, *Chasmosaurus belli* (Figure 1), was discovered in the middle strata of the Dinosaur Park Formation in Alberta and was originally named *Monoclonius belli* (Lambe 1902). Two additional species of *Chasmosaurus*, *C. russelli* and *C. irvinensis*, are currently recognized from elsewhere in the formation (Godfrey and Holmes 1995; Holmes et al. 2001; Ryan and Evans 2005). A further species, *C. mariscalensis*, has been described from the Aguja Formation in Texas (Lehman 1989), though it was recently given the new genus name *Agujaceratops* (Lucas et al. 2006) and may prove to be more closely related to *Pentaceratops* than to *Chasmosaurus* (Holmes et al. 2001; Diem and Archibald 2005).

Charles M. Sternberg (1927) reported on two specimens of *Chasmosaurus*, both identified as *C. belli*, on display at the National Museum of Canada (now the Canadian Museum of Nature) in Ottawa (Figure 2).

FIGURE 1. Life restoration of *Chasmosaurus belli*, based on CMN 2245. Illustration by JCM.

FIGURE 2. CMN 2280 (left) and CMN 2245 (right) on display at the National Museum of Canada (circa 1926). (Courtesy of the Canadian Museum of Nature).

As restored, the skeletons measured "approximately the same length but the bones of one… are much lighter in construction than those of the other" (Sternberg 1927: 67). According to Sternberg, the total length of the 'gracile' skeleton measured 4.93 m, while that of the "robust" skeleton measured 4.95 m. Unfortunately, their supports have since been disassembled and these original measurements cannot be verified. Sternberg attributed the difference in robustness between the two specimens to sexual dimorphism, stating, "it is thought that they represent male and female as it is common, among reptiles, for the female to be larger than the male" (Sternberg 1927: 67). This assumption has gone largely unchallenged in the literature (e.g., Lull 1933; Carpenter and Currie 1990; Dodson 1996), except for an implication by Godfrey and Holmes (1995) that the reported differences between the specimens do not reflect sexual dimorphism because they pertain to two separate species of *Chasmosaurus*.

The recognition of sexual dimorphism in a fossil species must begin with the establishment that the variation observed within that species does represent dimorphism. With only two reasonably complete skeletons of *Chasmosaurus belli* at his disposal, Sternberg could not have established this with certainty, and indeed, he neither quantified nor qualified the differences he observed between the specimens. It is also important to note that many of the bones were highly reconstructed with plaster and subsequently painted over so that the reconstructed portions cannot be easily identified. As chronicled by C. H. Sternberg (C. M. Sternberg's father) regarding the restoration of one of the skulls: "we had colored our plaster to resemble the fossil bone – no small task, by the way, as we had to learn to mix colors as well as do the work of a sculptor – with wax" (Sternberg 1917: 83). As such, the possibility remains that the difference in robustness between the two specimens might in part be attributable to the extensive restoration of certain elements. With these concerns in mind, we set out to identify and describe the variation noted between the skeletons, and conducted a reevaluation of Sternberg's original attribution of sexual dimorphism to *C. belli*.

Materials

The two *Chasmosaurus belli* skeletons (Figure 3) described by Sternberg (1927) reside in the collections of the Canadian Museum of Nature in Aylmer, Quebec. The "gracile" specimen was designated CMN 2245; the "robust," CMN 2280. CMN 2245 was collected from quarry Q037, and CMN 2280 from Q010, of the Dinosaur Park Formation (upper Campanian, ~75 Ma) in Dinosaur Provincial Park, Alberta (originally referred to by Sternberg [1927: 67] as the "Belly River series").

CMN 2245 (Figure 3A) is represented by the posterior half of a skull and mandibles (missing only the predentary), complete presacral series, synsacrum complete to the sixth sacral vertebra, twenty-four caudal vertebrae, most cervical and thoracic ribs, pectoral gir-

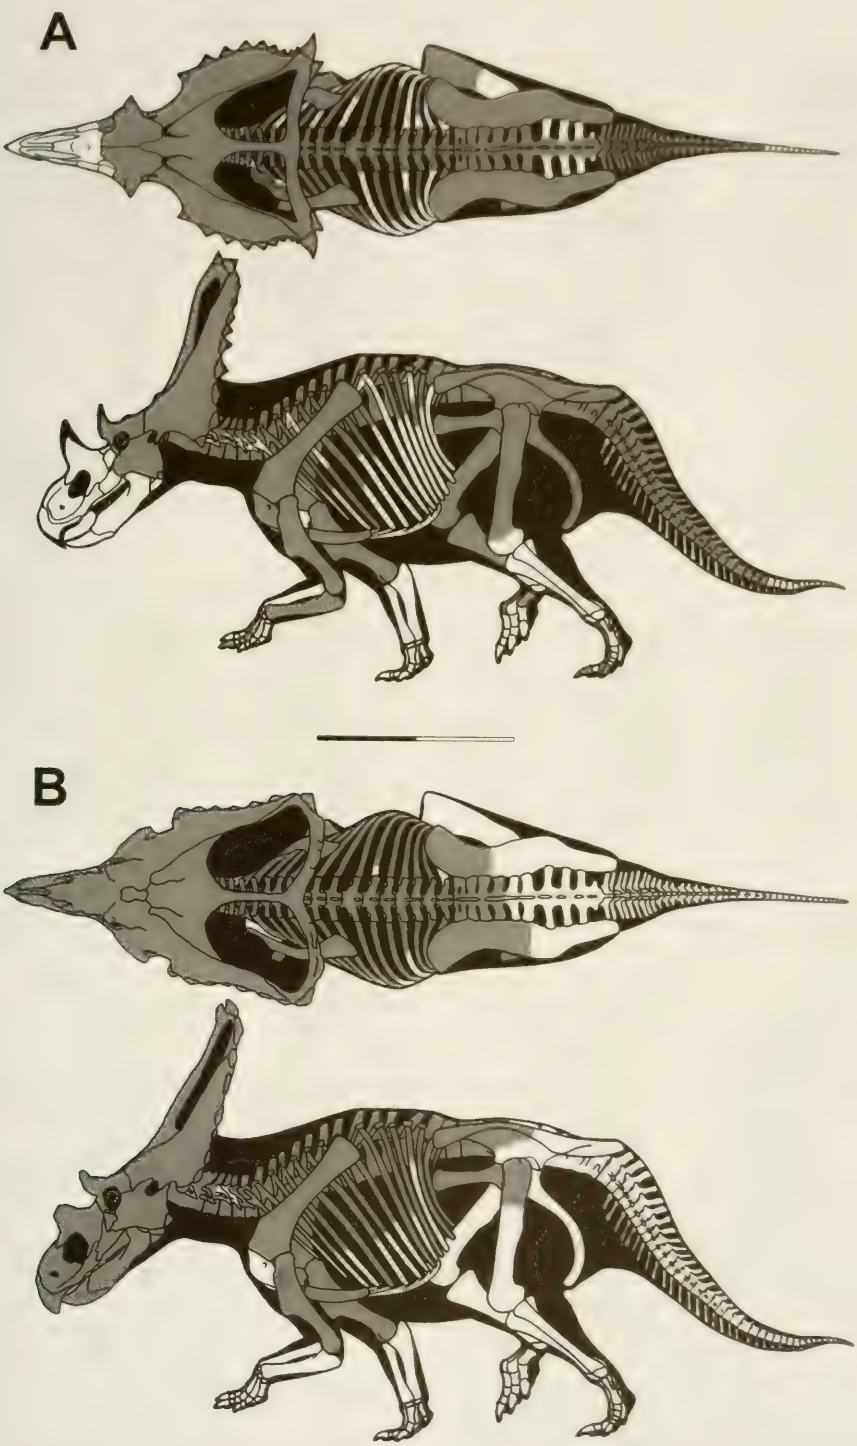

FIGURE 3. Material (in grey) attributed to (**A**) CMN 2245 and (**B**) CMN 2280. Scale bar = 1 m. Modified from original skeletal drawing by Gregory S. Paul. Used with permission.

dle (missing only the right coracoid), both humeri, left ulna, pelvic girdle, both femora, right tibia and fibula, and several carpal and tarsal elements.

CMN 2280 (Figure 3B) consists of a complete skull and mandibles, complete presacral series, synsacrum complete to the fourth sacral vertebra, most cervical and thoracic ribs, pectoral girdle (missing only the left coracoid), both humeri, anterior halves of both ilia, both pubes, and the proximal third of the left femur. A return visit to the quarry has yielded more hindlimb material, but it was in poor condition and not collected (D. H. Tanke, personal communication).

Overlapping material between the two specimens therefore consists of the posterior region of the skull, presacral and anterior sacral vertebrae, most ribs, most of the pectoral girdle, humeri, anterior ilia, pubes, and left proximal femur.

Methods

In order to facilitate distinction between the original bone and plaster, the brown paint was removed from many of the bones using acetone and a stiff-bristled brush. In some instances, the removal of the paint was not warranted when it was obvious that the element of interest had been created entirely of plaster (in which case a simple tap with the knuckle would confirm suspicion). In this way, the original elements common to CMN 2245 and CMN 2280 could be identified.

Three hundred and fourteen measurements were then taken from the postcranium of each specimen to the nearest millimetre, primarily according to the standards of Chinnery (2001). For those elements not considered by Chinnery, such as those belonging to the axial skeleton, one of us (JCM) devised our own measurement parameters. Measurements below 300 mm were generally taken with Mitutoyo SD type dial callipers and measurements above 300 mm were taken either with simple outside callipers and measuring tape or with large (1.04 m) Helios brand Vernier callipers. Circumferences were measured using a tailor's measuring tape. Angles were measured from photographs using a protractor. All available postcranial elements were measured, but only those bones deemed reliably complete and shared between the two skeletons were considered in this study.

Comparative Osteology

Description of Overlapping Material

Although CMN 2245 and CMN 2280 exhibit modest variability in the dimensions of their overlapping elements (Figure 4), much of this appears to be due to the extensive restoration and occasional postmortem deformation of the skeletons. Despite this, the best preserved elements usually differ in size by only a few percent, which is insufficient to produce visually discernable dimorphism, and is probably within the realm of individual variation that might be expected in tetrapods (e.g., Rising and Somers 1989; Zaaf and Van Damme 2001; Kelly et al. 2006). The coracoids of CMN 2245 and CMN 2280 are noticeably different in shape, although the left and only coracoid preserved in the former specimen has been badly weathered and highly reconstructed as a result, and is therefore of limited use. Only a few bones differ considerably in several dimensions and are described below.

Humerus

The humerus (Figure 4A) of CMN 2280 is considerably more robust than that of CMN 2245 in most dimensions (Table 1), particularly those of the humeral head, deltopectoral crest, and midshaft circumference. Besides proportional differences in the humerus, the insertional scar for the *latissimus dorsi* muscle on the deltopectoral crest is much less pronounced in CMN 2245.

Sternal Plate

Although the sternal plate (Figure 4B) is quite similar in size and shape between the two specimens, the process at the posterior end of the element extends 42-55% further laterally in CMN 2280 than in CMN 2245.

Presacral Vertebrae

The presacral vertebrae (Figure 4C) of these specimens are uniform in most dimensions, with most apparent differences being attributable to the addition of plaster. However, in the region of the withers (anterior thoracics), the vertebrae of CMN 2280 average 21% taller (Figure 5A) and their neural spines 19° more erect (Figure 5B) than in CMN 2245. Similarly, the transverse processes of the cervical and anterior thoracic vertebrae of CMN 2280 average 17° more erect than in CMN 2245 (Figure 5C), although this is difficult to state with confidence given the artificial coalescence of the vertebrae and the incompleteness of many of their spinous processes in CMN 2245. It seems, too, that the transverse widths of the vertebral centra anterior to the sixth thoracic average 10% wider in CMN 2280 (Figure 5D).

Discussion

Preservation of CMN 2245 and CMN 2280

While CMN 2245 is the most complete skeleton of *Chasmosaurus* known to date, it is less complete and less well preserved than generally supposed (e.g., Dodson 1996: 107). Some of the elements touted by Sternberg (1927) as being complete, such as the femora and caudal vertebrae, are actually only partially represented by nondescript scraps of bone buried in plaster, causing confusion among later authors (e.g., Lull 1933). Many of the presacral vertebrae have also been artificially "fused" together with plaster, obscuring much of the detail. CMN 2280 is by far the better preserved of the two specimens, although it is less complete. Consequently, there is only a moderate amount of material shared between the two specimens, and additional overlapping material would be desirable to make a convincing case for dimorphism in *C. belli*.

FIGURE 4. Dimorphic overlapping material of (**A**) CMN 2245 and (**B**) CMN 2280. **i**, right and left humeri; **ii** right and left sternal plates; **iii** posterior thoracic vertebrae in anterior (left) and left lateral (right) views. Note that, because of the poor preservation of the overlapping vertebrae, the eighth thoracic vertebra is figured for CMN 2245 and the tenth thoracic vertebra is figured for CMN 2280. Scale bar = 10 cm.

A Reevaluation of Sexual Dimorphism in Chasmosaurus belli

Recognizing sexual dimorphism in a fossil species is rarely a straightforward task, especially given small sample sizes where subtle but statistically significant dimorphic characters are difficult to resolve (Padian et al. 2005). Chinnery (2001, 2004) attempted to discern morphological variation, including sexual dimorphism, in the appendicular skeleton of the Ceratopsia, but could find none. The dimorphism originally ascribed by Sternberg (1927) to CMN 2245 and CMN 2280 was presumably based on variation in the postcranial skele-

TABLE 1. Selected measurements (after Chinnery 2001) for left humeri of CMN 2245 and CMN 2280, showing the large differences between their dimensions. Dimensions in square brackets are estimated.

Measurement parameter	Dimensions (mm)		Disparity
	CMN 2245	CMN 2280	(%)
Width of deltopectoral crest	95	72	24
Deltopectoral crest length, from external tuberosity to distal end of deltoid muscle scar	225	272	17.3
Craniolateral view; proximal width	44	76	42
Head height	[56]	78	28
Head width	55	86	36
Circumference about midshaft*	216	275	21.5

* = parameter not used in Chinnery (2001).

ton, although distinct differences in frill morphology are also present (see below). These differences cannot be attributed to either allometry or ontogeny since both specimens are of comparable size. Nor are they likely due to geographic variation since both specimens were found less than nine kilometres from one another. Post-mortem distortion cannot account for the differences either, as most of the elements are relatively uncrushed.

A review of the overlapping material reveals that the most striking differences between CMN 2245 and CMN 2280 lie with the humerus. The disparity in the robustness of the humerus and in the size of the insertional scar for the *latissimus dorsi* muscle seems to follow the prediction made by Chapman et al. (1997) that sexual dimorphism in ceratopsians would be expressed in the limb bones. It is also reminiscent of the condition seen in the humerus of many pachypleurosaurid sauropterygians (e.g., Sander 1989; Cheng et al. 2004) and of the sauropod *Camarasaurus* (Ikejiri 2005). However, if these humeral characters alone separate male from female, then other specimens of *Chasmosaurus belli* should exhibit the same disparity in humeral robustness as well. A bivariate plot derived from a Principle Components Analysis by Chinnery (2001: 134) revealed that the humerus of CMN 2245 plots as an outlier from the other eleven *Chasmosaurus humeri* included in the study. As the deviation lies along the y-axis, the differences are likely due to shape rather than size. Thus, while the shape differences between the humeri of CMN 2245 and CMN 2280 are real, the highly asymmetrical sex ratio implied is very unlikely. The inability of Lehman (1990) to identify dimorphism in the humeri from a population of *C. mariscalensis*, and M. J. Ryan's (personal communication) failure to find the same in several populations of *Centrosaurus apertus*, further supports this position. Sternberg (1927) specifically states that "[t]here have been no bones of other individuals used in the mounts", so the differences cannot be ascribed to the incorporation of material from a smaller individual into the mount. It seems that the humeri of CMN 2245 are simply unusually small and gracile, although the reason for this is unclear.

The reasons for the disparity in the dimensions of the sternal plates and of the presacral vertebrae are likewise uncertain in the absence of more material. The apparently longer and more erect neural spines and transverse processes of CMN 2280 coincide with observations made by Tereshchenko (2001) of protoceratopsids, in which the spinous processes of the vertebrae were reputedly shown to be longer and more erect in males than in females. If this apparent dimorphism is sexual, however, it would imply the "robust" specimen (CMN 2280) was male rather than female (*contra* Sternberg 1927). This type of "normal" sexual dimorphism, in which the male is more massive than the female, is typical of most reptiles (Fitch 1981; Shine 1989; Brochu 2002).

Thus, undoubted differences (albeit fewer than originally implied by Sternberg) between the two specimens do exist. The marked difference in the size and shape of the humerus may simply be anomalous, unless we accept the unlikely hypothesis that of the twelve *Chasmosaurus humeri* measured by Chinnery (2001), eleven are of one sex and only one is of the other. Other differences, such as the specific shape of the sternal plates and the relative size and orientation of the spinous processes of the presacral vertebrae, might represent sexual dimorphism or intraspecific variation. It is also possible that all of the postcranial discrepancies noted here are functionally related, reflecting a developmental compensation of the extrinsic muscles of the forelimb in response to the atrophied humeri of CMN 2245. However, in the absence of a statistically significant sample, it is impossible to resolve this question. Whatever the significance of the variation, there seems little choice but to reject the hypothesis of sexual dimorphism.

Two-Species Hypothesis

It is possible that the few differences documented here within the postcranial skeletons of CMN 2245 and CMN 2280 may simply reflect that these two specimens represent separate species. In a review of the systematics of the genus *Chasmosaurus* (Godfrey and Holmes 1995), two species were diagnosed based on differences in parietosquamosal frill structure. *C. belli* was defined as possessing a "parietal frill with nearly straight transverse posterior bars, each bearing one large

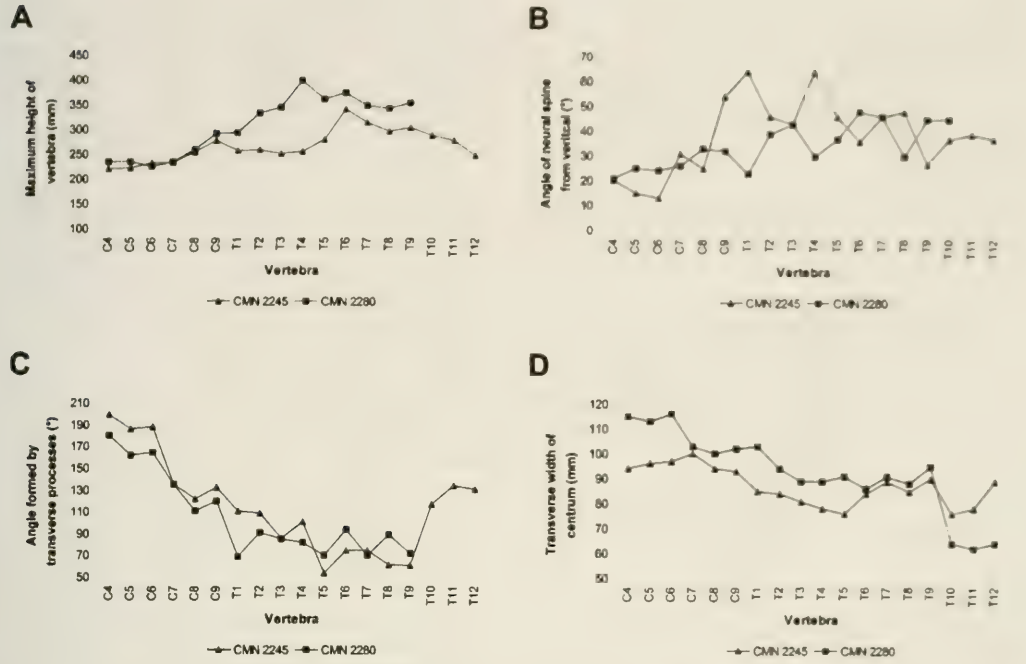

FIGURE 5. Graphical depictions of vertebral disparity between CMN 2245 and CMN 2280. **A**, Differences between maximum heights of vertebrae. The anterior thoracic vertebrae of CMN 2280 are consistently taller than those of CMN 2245. **B**, Differences between angles of neural spines. In the anterior thoracic region, the neural spines of CMN 2245 are angled further posteriorly than in CMN 2280. **C**, Differences between angles formed by transverse processes. The transverse processes of the cervical and anterior thoracic vertebrae of CMN 2280 are more erect than those of CMN 2245. **D**, Differences between transverse widths of centra. The cervical and anterior thoracic centra of CMN 2280 are consistently wider transversely than those of CMN 2245. Abbreviations: C, cervical vertebra; T, thoracic vertebra.

triangular epoccipital on its posterolateral corner; other parietal epoccipitals variable in number and degree of coossification with the parietal, but always much smaller. The lateral bar of the parietal completely encloses the parietal fenestra." *C. russelli* was characterized as having a frill in which the posterior margin is "broadly arched on either side of [the] median emargination. Each side bears three low triangular, roughly equal-sized epoccipitals. The lateral ramus of the parietal is reduced and does not completely encircle the fenestra in all but one specimen, permitting the squamosal to form a part of its lateral border." Under these amended diagnoses, CMN 2245 was retained within the hypodigm of *C. belli*, but CMN 2280 was reassigned to *C. russelli*. This distinction was challenged by Lehman (1998), who argued that the discrete characters used to distinguish *C. belli* from *C. russelli* actually represent end-members of a gradational spectrum of frill morphologies. In support of his argument, Lehman (1998: figure 9) figured seven skulls attributed to *C. belli* and *C. russelli*, illustrating the range of frill morphologies he observed. However, the lateral parietal bars of AMNH 5402 used by Lehman are not illustrated as being complete as they are in the original specimen, which creates the false impression that the frills exhibit graded variation. Correcting for this splits the series into two discrete groupings of frill morphologies (Figure 6), the contents of which agree with the original hypodigms of Godfrey and Holmes (1995).

Further support for the distinction between *C. belli* and *C. russelli* stems from their stratigraphic segregation within the Dinosaur Park Formation (Figure 7). This observation was made previously by Godfrey and Holmes (1995) and Holmes et al. (2001), and more recent quarry data support this claim, with *C. russelli* confined to the lower part of the formation and *C. belli* located much higher in the section (Ryan and Evans 2005). These independent lines of evidence strongly suggest that the variation between CMN 2245 and CMN 2280 is interspecific in nature, negating Sternberg's case for sexual dimorphism. Stratigraphic separation has also been noted recently among the supposedly sexually dimorphic lambeosaurine hadrosaurids of the Dinosaur Park Formation (Evans et al. 2006),

suggesting a need for more critical consideration of sexual dimorphism in the fossil record.

Conclusion

After a careful review of CMN 2245 and CMN 2280, it seems that the postcranium of neither specimen is quite as complete or as well preserved as originally described by Sternberg (1927). Consequently, the case for dimorphism (sexual or otherwise) is weaker than previously thought. Most of the variation exhibited by the shared elements is attributable either to poor reconstruction, postmortem distortion, or individual variation. Exceptional cases involve the humeri, sternal plates, and presacral vertebrae.

While the disparity in the shape of the humerus is indeed genuine, the same dimorphism is not seen in other specimens of *Chasmosaurus*, so this feature is likely anomalous rather than dimorphic. The sternal plates of CMN 2245 and CMN 2280 differ in the lengths of their posterolateral processes, and the presacral ver-

tebrae differ in the lengths and orientations of their spinous processes. However, analysis of additional *Chasmosaurus* material – preferably derived from some yet undiscovered monodominant bonebed (Eberth and Getty 2005) – would be necessary to determine the significance of this variation with regards to sexual dimorphism. The results presented here are therefore only preliminary, pending further investigation of individual variation in the ceratopsian postcranial skeleton.

Finally, previous detailed reviews of the frill morphology of either specimen seem to suggest that CMN 2245 and CMN 2280 may, in fact, belong to separate species (*C. belli* and *C. russelli*, respectively), as first put forth by Godfrey and Holmes (1995). This view is further supported by the stratigraphic segregation of the two specimens within the Dinosaur Park Formation of Alberta. Whether the postcranial differences identified here represent interspecific distinctions remains to be demonstrated. Therefore, although there do seem to be a few legitimate differences between the two specimens, the weight of the evidence so far accumulated does not support sexual dimorphism as Sternberg (1927) first suggested it, and there remains little choice but to reject this hypothesis. In the future, sexual dimorphism should be attributed to fossil species only when statistical significance and stratigraphic control have been demonstrated. Claims made in the absence of such evidence should be regarded with scepticism.

Acknowledgments

We would like to thank Gilles Danis, Margaret Feuerstack and Kieran Shepherd for offering access to specimens in their care. Philip Currie and Hans Larsson provided valuable resources and discussion. Andrew Farke, Michael Ryan, and two anonymous reviewers provided constructive criticism on earlier versions of this manuscript. This research stems from a B.Sc. Honours thesis written by JCM under the supervision of RH.

Catling, Paul M., Raymond Hutchinson, and Paul M. Brunelle. 2006. Use of saltmarsh by dragonflies (Odonata) in the Baie des Chaleurs region of Quebec and New Brunswick in late summer and autumn. Canadian Field-Naturalist 120(4): 413–420.

During late summer and autumn, in the Baie des Chaleurs region of Quebec, 18 species of adult dragonflies were recorded during one or more visits of at least 2 hours each to 14 saltmarshes. Three species, *Aeshna canadensis*, *Sympetrum danae* and *S. internum*, were present in more than half of the sites. The most abundant species was *S. internum* with over 100 seen at some locations. Adults of several species, including *Aeshna canadensis*, *A. umbrosa*, *Enallagma civile*, *E. hageni*, *Ischnura verticalis*, *Lestes disjunctus*, *Libellula quadrimaculata*, *Sympetrum danae*, *S. internum* and *S. obtrusum*, occurred in relatively high frequencies in both Baie des Chaleurs saltmarshes and in those elsewhere in Acadia. Within Baie des Chaleurs observations of emergence and/or presence of larvae, as well as regional abundance, were recorded for *Aeshna canadensis*, *A. umbrosa*, *Ischnura verticalis*, *Sympetrum costiferum*, *S. internum* and *S. vicinum*. Oviposition in saltmarsh pools was recorded for *Aeshna canadensis*, *Enallagma civile*, *E. hageni*, *Ischnura verticalis*, *Lestes congener* and *Sympetrum danae*. The saltmarsh dragonfly fauna of Baie des Chaleurs is significantly different from that of the rest of Acadia based on frequencies predicted from the latter region. To a large extent this difference is a result of significantly increased use of saltmarsh habitat by adults of six species including *Lestes congener*, *Sympetrum danae*, *Aeshna canadensis*, *Sympetrum costiferum*, *Lestes disjunctus*, and *Sympetrum internum* (in order of decreasing significance) in Baie des Chaleurs in comparison with saltmarshes elsewhere in Acadia. Local amelioration of salty conditions in certain saltmarshes, superimposed on regional amelioration as a result of protection from storms and saltwater dilution in the Baie des Chaleurs estuary, may contribute to an environment where adaptation can occur or where already tolerant species can exist. Dragonflies use saltmarsh habitat on the northeast coast of North America more extensively than is currently documented.

Key Words: Odonata, dragonflies, saltmarsh, Baie des Chaleurs, Quebec, New Brunswick.

Dragonflies are generally not highlighted as a group of insects that inhabits saltmarshes (e.g. Cheng 1976). Foster and Treherne (1976) outline the difficulty of characterizing marine insects because many species wander in from adjacent habitats. They define marine insects as having a "habitual requirement for some part of the saltmarsh environment at some stage of their life cycle." They show Odonata species comprising 3% of saltmarsh insect fauna which is dominated by Diptera, Coleoptera and Hemiptera which collectively make up 75% of the species. Corbet (1999, page194) notes the only truly marine dragonfly is *Erythrodiplax berenice*, but that there is also a "heterogenous assemblage of Zygoptera and Anisoptera that occupy brackish waters, usually of relatively low salinity compared with seawater."

Dragonflies have been reported to prey on saltmarsh tabanid flies and mosquitos, both groups of aggressive biting insects that interfere with human activities. As a consequence, questions periodically arise as to the extent of use of saltmarsh by dragonflies. Very little information on this subject is available for the maritime region of eastern Canada. Hutchinson and Bélanger (1999, 2004) have reported on adults of *Sympetrum danae* and *Enallagma civile* (respectively) using saltmarsh in the Baie des Chaleurs region. These observations suggest that use of saltmarsh by dragonflies may be more extensive than suspected. Preliminary observations in the Baie des Chaleurs region of Quebec and New Brunswick supported this view and suggested the use of saltmarsh by widespread species of dragonflies.

The objective of the work reported here was to summarize information on the late summer and fall use of saltmarsh by dragonflies in this region and to provide a basis for further analysis of evolutionary and ecological aspects of occurrence.

Methods

The study area – Baie des Chaleurs

Baie des Chaleurs is bounded on the north by the Gaspé Peninsula and on the south by northern New Brunswick (Figure 1). Flowing into it at its far western end is the Restigouche River, famous for fishing of Atlantic Salmon, *Salmo salar*. The tides are approximately 2 m high in the western basin and seawater is encountered in the estuary where it expands at Campbellton, New Brunswick. More information on Baie des

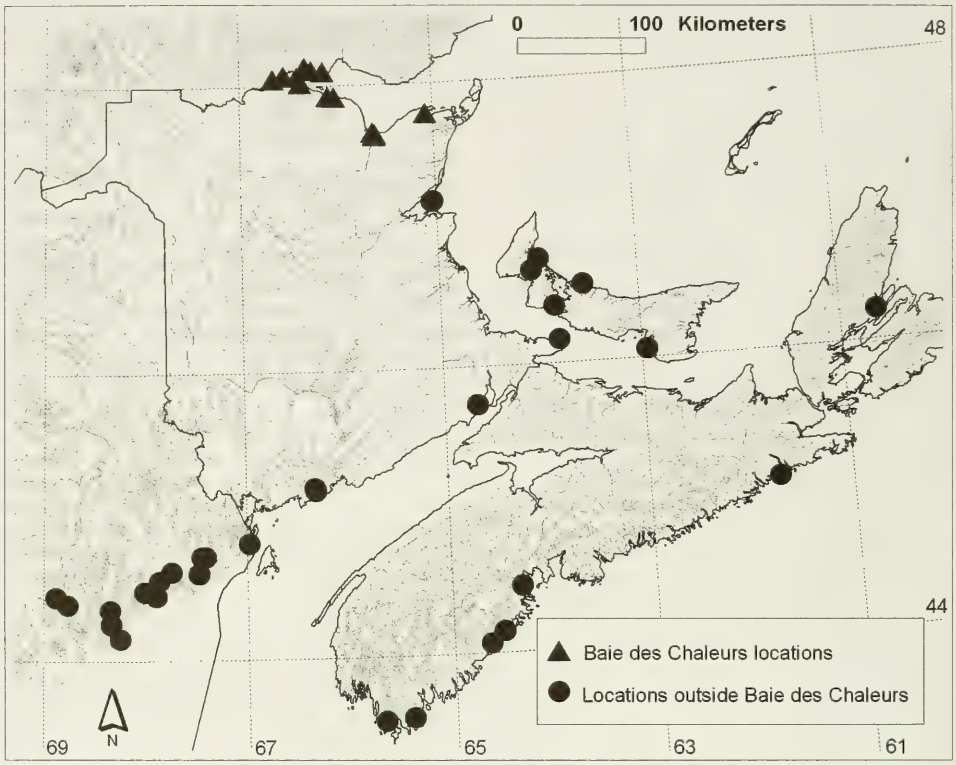

FIGURE 1. Region of Acadia showing saltmarshes visited in Baie des Chaleurs (triangles) and elsewhere (dots).

Chaleurs is available from Gauthier (2005), but there is apparently little information other than this recent reference (National Wetlands Working Group 1988).

Data gathering

Summarized below for the Baie des Chaleurs region are our late summer and fall observations of dragonflies in saltmarshes as well as some from the Atlantic Dragonfly Inventory Project (ADIP 2007*) for the same region. These observations cover the period from 22 July to 1 October over the past decade. The period of observation at any of these sites was at least 1-2 hours on any particular date. A list of observations at each site is followed by an annotated list of species and additional summary comments. In discussing the observations, the term "frequent" indicates a species seen often (e.g. at many sites) whereas "abundant" refers to a relatively large number of individuals at one or more sites.

All of the sites noted were dominated by plant species considered to be obligate halophytes, including two species of *Spartina* (*S. alterniflora* and *S. patens*), and *Ruppia maritima* was present in pools at most sites. The presence of these and other obligate halophytes indicates clearly that the sites were saltmarshes subject to periodic inflow of saltwater. Voucher specimens for the records of dragonflies for Baie des Chaleurs and elsewhere in Acadia are at the Canadian National Collection at the Agriculture and Agri-food (AAFC) Central Experimental Farm in Ottawa (Canadian National Collection CNC), and in the insect collections of the Nova Scotia Museum (NSMNH), the New Brunswick Museum (NFM) and the personal collection of P. M. Brunelle.

Comparisons

To explore differences between dragonfly occurrence in Baie des Chaleurs and elsewhere on the North Atlantic coast, the number of sites recorded for species of dragonflies in Baie des Chaleurs was compared with similar data (ADIP 2007*) for the rest of Acadia (Canadian Maritime Provinces and the state of Maine) outside of Baie des Chaleurs. Only records for the period from 22 July until the end of October are included in the comparison to represent late summer and autumn use of saltmarshes, and all records are for the past decade. Number of sites where a species was present was expressed as a percentage of total saltmarsh sites visited. The extent to which the Baie des Chaleurs dragonfly fauna is different was explored us-

FIGURE 2. Brackish pool in saltmarsh at St. Omer (site 4) where two females of *Sympetrum danae* were seen ovipositing in the foreground bed of floating algae and *Ruppia maritima*. The pool is surrounded by *Scirpus* spp., *Juncus gerardii* and *Spartina alterniflora*. Eight male *Sympetrum danae* patrolled the edge of this 25 m^2 pool, which is inundated by saltwater during high spring and fall tides.

ing a Chi-square test and percentage frequency elsewhere in Acadia to predict percentage frequency in Baie des Chaleurs. The test also allows the comparison of Chi-square values for individual species, but considering the sample size, the values are most useful to identify species contributing substantially to differences between Baie des Chaleurs and elsewhere, rather than to indicate a specific level of significance.

Results

Sites and species present

For each site, observation dates are given followed by species in alphabetical order and number of individuals seen in brackets. The total for each site and the size and nature of the area surveyed are also given. In cases where we are not the observers, the observers are listed at the end. A total of 18 species of Odonata was encountered in 14 saltmarshes in the Baie des Chaleurs in late summer and autumn.

(1) Bathurst (Queen Elizabeth and Youghall streets), New Brunswick (47.6648°N, 65.6328°W), 14 August 2005: *Aeshna canadensis* (25), *Enallagma hageni* (40), *Libellula quadrimaculata* (2), *Somatochlora elongata* (4), *Sympetrum costiferum* (5), *S. internum* (25), *S. vicinum* (4). Total: 7 species. Size: The site included a brackish ½ acre pool.

(2) 4 km E of Pointe-à-la-Croix, Quebec (48.0520°N, 66.6528°W), 15 August 2005: *Aeshna canadensis* (30), *Lestes congener* (4), *Lestes disjunctus* (2), *Sympetrum costiferum* (1), *S. danae* (9), *S. internum* (200), *S. obtrusum* (2). Total: 7 species. Size: 50 acres traversed, including creeks, pools and a river.

(3) Pointe-à-la-Garde, Quebec (48.0773°N, 66.5425°W), 15 August 2005: *Aeshna canadensis* (50), *Enallagma hageni* (43), *Lestes congener* (10), *L. disjunctus* (5), *Sympetrum costiferum* (1), *S. danae* (15), *S. internum* (150). Total: 7 species. Size: 10 acres traversed with many pools and creeks.

(4) Saint-Omer, Quebec (48.1087°N, 66.2514°W), 15 August 2005: *Aeshna canadensis* (18), *Lestes congener* (5), *L. disjunctus* (1), *Enallagma hageni* (1), *Sympetrum danae* (15). Total: 5 species. Size: 3 acres with pools beside creek (Figure 2).

(5) Charlo, New Brunswick (48.0182°N, 66.3666°W), 16 August 2005: *Aeshna canadensis* (1), *Lestes congener* (3), *Sympetrum danae* (1), *Sympetrum internum* (2). Total: 4 species. Size: ½ acre with one small pool.

(6) Nash Creek, New Brunswick (47.9229°N, 66.0840°W), 16 August 2005: *Aeshna canadensis* (6), *Sympetrum danae*

TABLE 1. Locations of saltmarshes visited in Baie des Chaleurs and elsewhere in Acadia over the past ten years within the period 22 July to 1 October. The order is increasing latitude from left to right and top to bottom.

(1), *S. internum* (4), *S. obtrusum* (1). Total: 4 species. Size: 5 acres with pools and creeks.

(7) Jacquet River Marsh, New Brunswick (47.9166°N, 66.0241°W), 16 August 2005: *Aeshna canadensis* (30 adults 1 larva probably this species), *Aeshna umbrosa* (1 larva probably this species), *Lestes congener* (50), *L. disjunctus* (1), *Ischnura verticalis* (200 adults, 4 larvae), *Sympetrum danae* (1), *S. internum* (5). Total: 7 species. Size: traversed 10 acres with pools and creeks.

(8) North of Eel River, New Brunswick (48.0657°N, 66.4000°W), 16 August 2005: *Aeshna canadensis* (22), *A. interrupta* (3), *Enallagma civile* (26), *Enallagma hageni* (1), *E. ebrium* (1), *Ischnura verticalis* (100), *Lestes congener* (10), *L. disjunctus* (4), *L. forcipatus* (2), *Sympetrum internum* (70), *S. obtrusum* (40). Total: 11 species. Size: at least 50 acres traversed with numerous creeks and pools, all brackish, at least periodically.

(9) Carleton, Quebec (48.1000°N, 66.1348°W), 29 September–1 October 2004: *Aeshna umbrosa* (5+), *Enallagma civile* (3), *Sympetrum danae* (7), *S. internum* (1), *S. vicinum* (1); *S. costiferum* (1); 10 September 1999, *Enallagma civile* (2), *Sympetrum danae* (4); 4 September 1995, *Sympetrum danae* (3), *Sympetrum* sp. (1 reddish specimen). Total: 6 species. Size: pools within an area of 3 acres.

(10) Bonaventure, Quebec (48.0500°N, 65.4833°W), 3 September 1995: *Aeshna* sp. (2), *Pantala flavescens* (1), *Sympetrum costiferum* (1), *S. danae* (10). Total: 4 species. Size: 3 acres.

(11) Nouvelle (saltmarsh of the Nouvelle River Basin), Quebec (48.1333°N, 66.3166°W), 4 September 1995: *Lestes congener* (1), *Sympetrum danae* (1), *Sympetrum* sp. (1, reddish). Total 3 species.

(12) Caraquet Bay, New Brunswick (47.7846°N, 65.0841°W) saltmarsh, 12 August 2002: *Sympetrum danae* (3), *Sympetrum internum* (1), *Sympetrum obtrusum* (1). Observer: Dwayne L. Sabine. Total: 3 species.

(13) Daly Point Marsh, Bathurst Harbour, New Brunswick (47.64°N, 65.62°W), 12 August 1993: *Sympetrum danae* (1). Observer: Reginald P. Webster. 21 July 1999, *Libellula quadrimaculata* (2), *Aeshna canadensis* (2). Total 3 species.

(14) Carron Point Marsh, Bathurst Harbour, New Brunswick (47.65°N, 65.61°W), 22 July 1999: *Aeshna canadensis* (1), *Libellula quadrimaculata*, *Sympetrum danae* (2), *Sympetrum obtrusum* (1). Total: 4 species.

Annotated List of Species (alphabetical order)

Aeshna canadensis: at 10 sites and frequent at some, apparently uses saltmarsh regularly as an adult hunting on salty pools of the outer marshes which are influenced by tides regularly, as well as inner brackish pools; seen to oviposit in saltmarsh pools. A larva 20 mm long that was probably (but not definitely, due to difficulty of identifying young larvae) referable to this species was retrieved from a periodically brackish pool dominated by *Ruppia maritima* (site 7).

Aeshna interrupta lineata: only one at one site but of interest because this subspecies exists at low frequencies in the Atlantic provinces and is largely confined to the Gulf of St. Lawrence area. The specimen was referred to subspecies *lineata* on the basis of uninterrupted lateral stripes. This species is reported to tolerate saline waters (Dunkle 2000).

Aeshna umbrosa: only from two sites but five adults seen patrolling saltmarsh ponds; at the other site two young larvae probably referable to this species (21 and 23 mm long) were found in a brackish pool dominated by *Ruppia maritima* (site 7) – due to their small size, identification is tentative; mature larvae of this species were found in water-filled pockets within the storm splash zone of a sea cliff near Port-au-Saumon, Quebec (Hutchinson 1999); and D. Sabine (personal communication) found larvae in a small depression pool in a seaside boulder within the tidal splash zone on the Fundy shore of New Brunswick.

Enallagma civile: two sites; twenty-six captured (most released), many paired, were flying over a periodically brackish creek in saltmarsh with mostly *Ruppia maritima*, also *Zannichellia palustris*, *Potamogeton pectinatus*, lined by *Spartina alterniflora* (site 8). *Enallagma civile* was first reported from this region by Hutchinson and Bélanger (2004), and their report was from a saltmarsh habitat at Carleton (site 9), where they observed oviposition behaviour (but did not actually see eggs). Osborn (1906) reported a tolerance of brackish water.

Enallagma ebrium: only one at one site, so likely vagrant.

Enallagma hageni: At four sites and abundant at two; 40 seen and several ovipositing on *Ruppia maritima* around a brackish, ½ acre pool with dense beds of *Ruppia maritima* surrounded by *Spartina alterniflora*, *S. patens*, *S. pectinata*, and *Carex*

TABLE 2. Comparison of species of dragonflies recorded from Acadia outside of Baie des Chaleurs and Baie des Chaleurs based on number (left) and percentage (right) of total saltmarsh sites visited. Acadia includes the Maritime Provinces (Nova Scotia, New Brunswick and Prince Edward Island) of Canada and the state of Maine. Records from Acadia are from the ADIP database (2007). Records from Baie des Chaleurs are those reported here and are also in ADIP 2007. Only records for the period from 22 July until the end of October are included in the comparison to represent late summer and autumn use of saltmarshes. Chi-square values for each species based on comparison of frequency elsewhere in Acadia to predict frequency in Baie des Chaleurs are included to highlight species most different in their occurrence in these two regions in bold. Names are taken from Catling et al. (2005).

Species	Acadia n = 32		Chaleurs n = 14		Chi-square

paleacea, flooded by high tides in fall according to local residents (site 1); 43 around pools and creeks with *Ruppia maritima*, *Zannichellia palustris*, *Potamogeton pectinatus* and *Enteromorpha* sp. (site 3).

Ischnura verticalis: abundant at each of two locations; more than 200 seen around pools with *Potamogeton pectinatus* and *Ruppia maritima* with *Spartina pectinata* fringe, some ovipositing, and at the the same location four larvae 17-21 mm long referable to this species were collected from the pools (site 7); more than 100 were seen around spring-fed pools surrounded by *Spartina pectinata*, *Spartina alterniflora, Spartina patens* and species of *Scirpus* (site 8). In both cases the pools were fed by freshwater springs but were definitely subject to saltwater during high tides.

Lestes congener: at seven sites and at least 82 individuals overall; given the number of sites and the number of individuals this species may be a resident of saltmarsh; several pairs seen ovipositing on *Juncus balticus* and *Juncus gerardii* around brackish pools with *Potamogeton pectinatus* and *Ruppia maritima* (site 7).

Lestes disjunctus: at five sites; but not as abundant as *L. congener*.

Lestes forcipatus: only one at one location.

Libellula quadrimaculata: at three sites; adults patrolled a brackish pool at site 1; said to tolerate saline waters (Dunkle 2000).

Pantala flavescens: only one at one location and probably a migrant.

Somatochlora elongata: only found at one location, but four seen over pool with *Ruppia maritima* surrounded by *Spartina alterniflora, S. patens, S. pectinata*, and *Carex paleacea*, flood-

ed by high tides in fall according to local residents (site 1). This species has also been reported from four other saltmarshes in Acadia (Table 2).

Sympetrum danae: at 12 sites, and abundant on the north side of the bay, patrolling saltmarsh pools very much like *Erythrodiplax berenice* does in saltmarshes further south on the Atlantic coast. Two females were seen ovipositing in a pool 25 m^2 with a thick bed of *Ruppia maritima* surrounded by *Scirpus* spp., *Juncus gerardii* and *Spartina alterniflora* (site 4, Figure 2). The pool was said by local people to be flooded by high tides in spring and fall. Ovipositing behaviour was also observed in saltmarsh ponds at Carleton but eggs were not actually seen. The species appears to be less frequent in the saltmarshes on the south side of the bay. Hutchinson and Bélanger (2004) have previously drawn attention to the utilization of saltmarsh by adults of this species and suggested the possibility that larvae may mature in brackish pools. High salinity of spring and fall high tides may be avoided by the resistant egg stage that overwinters. Larval development may be relatively rapid (Corbet 1999) and allow use of saltmarsh pools during periods of minimal tidal impact. Although the larval habitat of this species is widely reported in both Europe and North America as oligotrophic pools and small lakes on bogs and heathlands, it also inhabits very alkaline fens in eastern and northern Canada. Consequently saltmarsh pools would not be so remarkable a habitat. Interestingly in Ireland, males are said to be non-territorial (Nelson and Thompson 2000*), contrary to some of our observations on saltmarsh pools. In some places within its holarctic range, *S. danae* is reported to migrate (e.g. Corbet 1999, page 420). Ability to utilize brackish habitats may be beneficial to migrants over water in the maritime regions where landfall may have only brackish habitat.

Sympetrum internum: at nine sites and abundant at some. One emerging from a pool surrounded by *Spartina pectinata* in upper marsh (site 2) and tenerals in several sites; uses saltmarsh extensively as an adult and the upper marsh at least to some extent as larval habitat.

Sympetrum costiferum: at five sites; two emerging from brackish ½ acre pool with dense beds of *Ruppia maritima* surrounded by *Spartina alterniflora*, *S. patens*, *S. pectinata* and *Carex paleacea*, flooded by high tides in fall according to local residents (site 1); one emerging from sandy bottom creek with *Ruppia maritima* and *Enteromorpha* sp. (site 3). Apparently uses saltmarsh habitats for development but in low numbers, possibly due to limited amount of sandy larval habitat in most marshes. According to Walker and Corbet (1975), *S. costiferum* appears to be more tolerant of saline waters than other species of *Sympetrum*, but they are not clearly referring to sodium salts. Dunkle (2000) also refers to tolerance of saline waters.

Sympetrum obtrusum: at five sites but no strong evidence of use of saltmarsh as larval habitat by this widespread and generally abundant species.

Sympetrum vicinum: at two locations but at one of these two were emerging from brackish ½ acre pool with dense beds of *Ruppia maritima* surrounded by *Spartina alterniflora*, *S. patens* and *S. pectinata*, and *Carex paleacea*, flooded by high tides in fall according to local residents (site 1).

Discussion

Comparison with saltmarshes elsewhere in Acadia

A total of 35 species has been recorded from saltmarshes in Acadia (Table 2). Several occurred in relatively high frequencies in both Baie des Chaleurs saltmarshes and saltmarshes elsewhere in Acadia suggesting some degree of salinity tolerance. Included in this category are *Aeshna canadensis, A. umbrosa, Enallagma civile, E. hageni, Ischnura verticalis, Lestes disjunctus, Libellula quadrimaculata, Sympetrum danae, S. internum* and *S. obtrusum*.

With a Chi-square value of 912.707, the saltmarsh dragonfly fauna of Baie des Chaleurs is significantly (well below the 0.005 level) different from that of the rest of Acadia based on frequencies predicted from the latter region. Based on Chi-square values exceeding 10.0 (significance below the 0.005 level), Baie des Chaleurs saltmarshes differed from sites elsewhere in having significantly more sites for six generally widespread species that occur throughout Acadia (Table 2, Donnelly 2004a, b, c) including *Lestes congener, Sympetrum danae, Aeshna canadensis, Sympetrum costiferum, Lestes disjunctus*, and *Sympetrum internum* (in order of decreasing significance). Three species were significantly less frequent in Baie des Chaleurs including *Erythrodiplax berenice, Sympetrum semicinctum*, and *Lestes rectangularis* all of which do not extend as far north as Baie des Chaleurs (Donnelly 2004b, c). *Erythrodiplax berenice* for example does not occur north of 45°N, whereas Baie des Chaleurs is situated at 48°N.

General Observations

With 35 species of adult dragonflies recorded in saltmarshes in Acadia and 18 in Baie des Chaleurs, and in both cases, approximately half of them occurring in more than 15% of sites, substantial use by dragonflies is suggested. This is further supported by records of emergence, presence of larvae, ovipositing behaviour and relatively large numbers of individuals.

In a number of saltmarsh habitats further south on the coast of New England, the only abundant dragonfly species that we have observed using the saltmarsh habitat in late summer is the saltmarsh specialist, *Erythrodiplax berenice*. It is often present in large numbers (to 30 per acre), the males patrolling pools, the females along the marsh edges but pairs frequent over the marsh in early to mid-morning. Other Odonatists have also noted that in many saltmarshes the only dragonfly present is *E. berenice* (D. Paulson, personal communication). Other species fly over the marshes including the migratory *Anax junius*, *Tramea* spp., and *Pantala* spp. All of these may hunt over the marsh but seem much more often to hunt and congregate in open shrubby areas around the marsh edge. We have seen species of *Enallagma, Lestes* and *Sympetrum* only occasionally in these more southern saltmarshes. There may be a trend toward more extensive use of saltmarsh by dragonflies in a northerly direction. Possibly saltmarshes further south are less utilized by widespread dragonfly species because salt may be more concentrated in pools of upper marsh due to higher evaporation.

Baie des Chaleurs

The fact that Baie des Chaleurs saltmarshes differed from sites elsewhere in Acadia in having very significantly more sites for six generally widespread species, including *Lestes congener, Sympetrum danae, Aeshna canadensis, Sympetrum costiferum, Lestes disjunctus*, and *Sympetrum internum* (in order of decreasing significance), suggests either that there has been some adaptation to saltmarsh conditions by these wide-ranging species in this region, or that saltmarshes in this region are more readily colonized as a result of unique characteristics, or both. Baie des Chaleurs is home to an endemic and endangered saltmarsh butterfly, the Maritime Ringlet (*Coenonypha tullia nipisiquit,* McDunnough 1939). Recent studies have suggested that this butterfly has evolved physiological adaptation to saline wetland conditions including tolerance of tidewater submergence for up to 24 hours (Webster 1998; Sei 2004). The endemic but somewhat more widespread Maritime Copper Butterfly (*Lycaena dospassosi* McDunnough) is also confined to the saltmarshes of northern New Brunswick and Gaspé (Thomas 1980).

Unique charaterisitics of Baie des Chaleurs saltmarshes may be widespread or local, or both. Parts of saltmarsh are prohibitively salty for non-adapted species only during high tides in the spring and fall, and even then saltwater may be somewhat diluted due to the estuary effect. There are distinctive east and west basins and in the west basin, where most of our observations were made and where the Maritime Ringlet occurs, the tides are higher and salt concentrations lower than in the east basin (Gauthier 2005). It has been suggested that saltmarshes can be divided into two kinds, estuarine such as Baie des Chaleurs, and coastal (National Wetlands Working Group 1988). Although the difference between the two types is not perfectly clear, conditions of inundation and salt concentrations in coastal saltmarsh would be more severe.

Saltmarshes have periodic inundation in common, but the timing and duration may vary as well as the salt concentrations. Furthermore, occasional lack of ice development in the bay may result in severe impact of high tide associated with winter storms on some saltmarshes, while others may be protected by barrier beaches (Webster 1994*, 1998). Local amelioration of salty conditions in certain saltmarshes, superimposed on regional amelioration, may provide an environment where tolerant species can exist and adaptation can occur.

Tolerance of salt

Although the places where dragonflies were recorded in Baie des Chaleurs saltmarshes may not have been consistently high in salt concentration, they were definitely brackish, were part of a tidal salt marsh subject to periodic inundation with salt water and subject to salt to the extent of excluding non-halophytic flora. Species of dragonflies differ in their ability to cope with salt (Cannings and Cannings 1987). Of the 18 species found in Baie des Chaleurs, *Aeshna interrupta, Libellula quadrimaculata, Sympetrum danae*, and *S. costiferum* are reported by Dunkle (2000) to tolerate saline water. However, Walker (1953, 1958), Walker and Corbet (1975), Pilon and Lagacé (1998) do not report any of the species listed here as occurring in saltmarsh. Observations in Baie des Chaleurs suggest that dragonflies occupy saltmarshes to a greater extent than is currently documented. Ecological and evolutionary aspects, including extent to which local adaptation has occurred, require more study, particularly directed toward larval occurrences and comparisons with other habitats in the surrounding landscape.

Hanke, G. F., M. C. E. McNall, and J. Roberts. 2006. First records of the Yellow Bullhead, *Ameiurus natalis*, a loricariid catfish, *Panaque suttonorum*, and a Silver Pacu, *Piaractus* cf. *P. brachypomus*, in British Columbia. Canadian Field-Naturalist 120(4): 421-427.

In Canada, there are no native catfish west of the continental divide and until recently, the list of extant exotic catfishes in British Columbia only included introduced Black Bullhead (*Ameiurus melas*) and Brown Bullhead (*Ameiurus nebulosus*). We report that a single Yellow Bullhead (*Ameiurus natalis*) was collected from Silvermere Lake in the Lower Fraser River drainage. This represents the first record of the Yellow Bullhead in western Canada, and its introduction likely was accidental with a shipment of Largemouth Bass (*Micropterus salmoides*) rather than dispersal from Washington. Warm, eutrophic, weedy habitat in the Fraser Delta provides ample habitat for Yellow Bullheads and other exotic fishes. A Blue-eyed Panaque (*Panaque suttonorum*), a loricariid catfish found in 1995 in Shawnigan Lake, Vancouver Island, probably represents a single, illegally released aquarium fish, as does a large Silver Pacu (*Piaractus* cf. *P. brachypomus*), which was found in Green Lake on Vancouver Island in 2004.

Key Words: Yellow Bullhead, *Ameiurus natalis*, Blue-eyed Panaque, *Panaque suttonorum*, Silver Pacu, *Piaractus* sp., exotic introductions, British Columbia.

Most populations of native species were established in British Columbia during and after deglaciation, but this slow process of natural colonization and dispersal pales in comparison to the wave of accidental and intentional species introductions in the province since the arrival of Europeans. Escaped pets, intentionally released pets, the illegal and intentional release of exotic game fishes by local fishermen, intentional release of game fishes by government agencies, contaminants in poorly sorted shipments of game fish, and northward dispersal of fishes introduced in Washington, now are the principal sources of exotic freshwater fishes in British Columbia. The pathways used to enter the province and the dispersal potential once present, varies with each species.

Carl and Guiguet (1957), Carl et al. (1967), Scott and Crossman (1973), Hart (1973), Crossman (1991), Coad (1995), Moyle (2002), and Wydoski and Whitney (2003) detail the exotic fish species (or hybrids) known to have been introduced into British Columbia prior to this report (Table 1). Approximately 7.4% of the exotic fishes in Table 1 are ornamental (including Mosquitofish [*Gambusia affinis*] and Fathead Minnows [*Pimephales promelas*] introduced for mosquito control; Fathead Minnows also may be introduced illegally as live bait, or dispersed into the province via the Peace River drainage [Smith and Lamb 1976]), 24.1% are non-game fishes (e.g., stickleback, Redside Shiners [*Richardsonius balteatus*]), and 68.5% are game/food fishes and hybrids between game fish species. In many cases, fishes that are native to the province (or their hybrids) are legally stocked in new locations to enhance local fisheries and satisfy anglers (e.g., Walleye [*Sander vitreus*], Rainbow Trout [*Oncorhynchus mykiss*], West-slope Cutthroat [*O. clarki lewisi*], and Pacific salmon [*O. gorbuscha*, *O. nerka*, *O. keta*, *O. kisutch*, *O. tshawytscha*]), and in others, game fishes are illegally introduced to new waterbodies by private individuals (e.g., Northern Pike [*Esox lucius*], Smallmouth Bass [*Micropterus dolomieu*]) (McPhail and Carveth 1994). While most fishes released in this province are game fishes, it is likely that the number of exotic aquarium fishes released in British Columbia will grow with the burgeoning pet trade (see Padilla and Williams 2004).

Species Accounts

Silver Pacu (*Piaractus* cf. *P. brachypomus*) – Family Characidae (tetras)

On 4 June 2004, a large pacu was caught by a Federal Fisheries Officer angling in Green Lake (~49°13'50"N, 124°03'39"W) near Nanaimo (Figure 1). This fish likely is a Silver Pacu (Figure 2), although initially it was thought to be a piranha (*Serrasalmus* sp./*Pygocentrus* sp.) and subsequent media reports called the fish a Red-bellied Pacu (a commonly used name in the pet trade). The species identity as used in this report cannot be verified unless the body is located

TABLE 1. Fishes introduced British Columbia according to Wydoski and Whitney (2003), Moyle (2002), Coad (1995), Crossman (1991), Hart (1973), Scott and Crossman (1973), Carl et al. (1967), and Carl and Guiguet 1957, and Royal British Columbia Museum (RBCM) collection records; EX = exotic introductions, NA = native populations also in BC, MM = man-made hybrids or hybrids in nature due to stocking of exotics.

and examined in detail. Furthermore, only estimates of size can be taken from images and notes provided by staff of British Columbia, Ministry of Water, Lands, and Air Protection (now Ministry of Environment). The fish measured about 40 cm total length, and 35 cm fork length, and had been feeding on aquatic vegetation based on its gut contents (milfoil was the dominant item in the gut) [M. deLaronde, personal communication, 2005].

Blue-eyed Panaque

(*Panaque suttonorum*) – Family Loricariidae (suckermouth armoured catfishes)

The Royal British Columbia Museum fish collection contains a single Blue-eyed Panaque (RBCM 996-190-001) (Figure 3), which was collected in 1995 from a ditch where Royce Road crosses Shawnigan Creek (approximately at 48°40'05", 123°37'32") (Figure 1). The creek leads into the north end of Shawnigan Lake, Vancouver Island. The specimen is 21.8 cm total, and 19.2 cm fork length. This specimen originally was misidentified as *Hypostomus plecostomus* when it was received in 1996.

Yellow Bullhead

(*Ameiurus natalis*) – Family Ictaluridae (North America Freshwater Catfishes)

The first Yellow Bullhead found in British Columbia (Figure 4) was collected on 21 July 2005, by electrofishing the southeast corner of Silvermere Lake (49°10'01"N, 122°24'27"W) (Figures 1 and 5). The Yellow Bullhead was in stained but clear water about 10 cm deep, and emerged from a clump of submerged, algae-covered terrestrial grass which was approximately 30 cm offshore; the water in the bay was 29.5°C at the surface. The specimen (RBCM 005-079-001) was anaesthetized/euthanized with 2-phenoxy ethanol, prior to fixing in 10% formaldehyde. It is possible that other Yellow Bullheads have been caught in this lake, but were not recognized as different from Black or Brown Bullheads by local anglers. The specimen is 12.9 cm total length and 10.7 cm standard length. The following features from identification keys in Scott and Crossman (1973, page 589), Becker (1983, pages 143-145), Moyle (2002, pages 85-86), and Wydoski and Whitney (2003, pages 153-154), confirm the identification of the Yellow Bullhead from Silvermere Lake: body lacks spots or blotches; lower jaw does not project beyond upper jaw; distance between isthmus and lower jaw notch is less than the distance between the lower jaw notch and the tip of the lower jaw (see illustrations in Scott and Crossman 1973, page 589); mental barbels yellow-white without melanophores; depressed anal fin overlaps leading edge of caudal fin; and caudal fin with round trailing margin.

Yellow Bullheads are native to Atlantic and Gulf Slope drainages from New York to Mexico, the St. Lawrence River, the Great Lakes, and the Mississippi River Basin from North Dakota to the Gulf of Mexico (Scott and Crossman 1973; Lee et al. 1980), and they have been introduced to at least 14 states outside of their native range (Fuller et al. 1999). They also are known from headwaters of the Hudson Bay drainage in Minnesota but have not been found downstream in Manitoba to date (Koel and Peterka 1994; Stewart et al. 2001; Stewart and Watkinson 2004).

FIGURE 2. The single Silver Pacu (*Piaractus* cf. *P. brachypomus*) taken from Green Lake, Vancouver Island, 4 June 2004; surrounding parts of image (stainless-steel tabletop) cropped to simplify the illustration. Scale bar = 5 cm.

FIGURE 3. A photograph of the preserved *Panaque suttonorum* specimen (RBCM 996-190-001) collected from the Shawnigan Lake area, Vancouver Island; surrounding parts of image (dissection tray) cropped to simplify the illustration. Scale bar = 5 cm.

Discussion

Two of the three species documented in this report are not threatening to the ecology of British Columbia, especially since they are tropical and appear to result from the release of single fish rather than groups, which could form breeding populations. However, all three species are unnecessary additions to the provincial ichthyofauna, and there always is a risk that exotic introductions may carry unknown pathogens which may infect native fishes (e.g., Dove and Ernst 1998; Yamamoto and Tagawa 2000; Font 2003).

In British Columbia, a large portion of the northern waterways are fast-flowing, cool to cold glacier-fed streams and oligotrophic lakes running through montane areas, and as such, are inhospitable to warm water adapted exotic organisms. However, many exotic species can survive in the southwestern region for a summer or longer, and fortunately, cold meltwater from higher elevation may limit their long-term survival and dispersal. In some regions (e.g., the Okanagan, the Lower Fraser River Valley, and southern Vancouver Island), there are many ponds, ditches, reservoirs, and slowly flowing low-gradient streams running through agricultural land that may support a range of exotic species, and in places, may be warm enough in summer to allow tropical species to breed. The mild climate of southwestern British Columbia already is hospitable to a wide range of organisms presently in the pet trade (e.g., fishes such as *Lepisosteus osseus*, *L. platostomus*, *L. oculatus*, *Ictalurus punctatus*, *Clarias* sp., *Tanichthys albonubes*, *Rhodeus* sp., *Cyprinella lutrensis*, *Carassius auratus*, *Cyprinus carpio* [koi], *Myxocyprinus asiaticus*, *Misgurnus anguillicaudatus*, *Gastromyzon* sp., and some hillstream loaches [Homalopteridae]) or fishes imported live to Canada for human consumption (e.g., *Tilapia* sp., *Sarotherodon* sp., *Oreochromis* sp., *Channa* sp., *Hypophthalmichthys* sp., and *Monopterus* sp.). Given predictions of warming aquatic environments in North America (Mandrak 1989; Meisner 1990; Rahel et al. 1996; Eaton and Scheller 1996; Schindler 2001; Stefan et al. 2001; Jackson and Mandrak 2002; Vander Zanden et al. 2004) it is likely many more exotics could become established in the waterways of this province; those that already are present in Canada likely will expand their range northward where habitat and water flow permits.

Characid Fishes

The large size of most pacu and related "silver dollar" species limits their suitability for home aquaria, and likely is the reason why they are occasionally released in North America. Fuller et al. (1999) discuss a variety of pacu and silver dollars (*Colossoma* sp., *Metynnis* sp., *Myleus* sp., *Piaractus* sp.), which have been found outside of captivity in many of the United States including Washington. Coad (1995, page 11) noted that a specimen of *Colossoma bidens* was found in Ontario (although the location was not given), and Renaud and Phelps (2001) mention another pacu which was found in the Rideau Canal, Ontario. It is not known if there are any wild/naturalized reproducing populations of pacu and silver dollars in North America (Fuller et al. 1999).

Apparently the Silver Pacu found in Green Lake on Vancouver Island was the second pacu to be collected in British Columbia; the first was taken from the Lower Mainland a few years earlier (R. Dolighan, personal communication, 2005), but no detailed reports or literature references to this fish exist. It has been suggested that the Silver Pacu from Green Lake was from a large display aquarium in a local restaurant. The other pacu in the display aquarium also may have been released when the restaurant closed down, but attempts to locate other specimens in Green Lake were unsuccessful. The intentional release of large, unwanted aquarium pets (including large piranha [probably *Pygocentrus nattereri*] which may have been released into Langford Lake on Vancouver Island [T. Duce, personal communication, 2005]) is a continuing threat to British Columbia's waterways, and a threat which is difficult if not impossible to control. Piranhas such as *P. nattereri* have been found in the wild as far north as Minnesota, Idaho, and the Columbia River in Washington (Fuller et al. 1999). Fortunately pacu and piranha usually are kept in small numbers or singly, and so any released specimens are unlikely to find mates and reproduce, even if they survive in British Columbia's waters.

Loricariid Catfishes

Some loricariid fishes ("plecostomus") can tolerate cool water aquaria and commonly are kept with goldfish in home aquaria, as are weatherloaches (*Misgurnus anguillicaudatus*), and surprisingly, it is the expensive *Panaque* species, not the inexpensive *Hypostomus*, which have been found in the wild in Canada. In addition to the single Blue-eyed Panaque from British Columbia, a single specimen of the Royal Panaque or Royal "Pleco" (*Panaque nigrolineatus*), is known from southern Ontario (Coad 1995, page 11). Both the Royal Panaque and the Blue-eyed Panaque are native to South America and are unlikely to survive long in Canada's present climate, unless they are released downstream of hotsprings or near warm industrial effluent (the same can be said for most tropical fishes, including pacu). Illegally released tropical aquarium fishes persist in Alberta downstream of hotsprings despite cold winters in that province (Nelson and Paetz 1992), and the possibility of tropical fish introductions is a persistent threat to hotsprings in British Columbia.

Ictalurid Catfishes

Washington state waterways contain several ictalurid species, including: Blue Catfish (*Ictalurus furcatus*), Channel Catfish (*I. punctatus*), Tadpole Madtom (*Noturus gyrinus*), Flathead Catfish (*Pylodictis olivaris*), White Catfish (*Ameiurus catus*), Yellow Bullhead (*A. natalis*), Black Bullhead (*A. melas*), and Brown Bull-

head (*A. nebulosus*) (Wydoski and Whitney 2003). None of these fishes are native to the state and exhibit varying degrees of success in Pacific slope drainages. Black, Brown, and Yellow Bullhead catfishes now are found all over Washington (Wydoski and Whitney 2003), but since casual observers find the three species difficult to differentiate, it is likely that the true range of each is underestimated.

Carl et al. (1967), Scott and Crossman (1973), McPhail and Lindsey (1986), McPhail and Carveth (1994), and Coad (1995) detail the distribution of catfishes in British Columbia and until this year, researchers thought that only the Black Bullhead and Brown Bullhead existed in this province. As in Washington, the range of Black and Brown bullheads likely is underestimated because of the difficulty of identification, and limited survey sampling in appropriate habitat.

Yellow Bullheads are hardy, and given their presence in the Columbia River system and the Olympic Peninsula in Washington (Wydoski and Whitney 2003), it was only a matter to time before they appeared in British Columbia. It is possible that Yellow Bullheads were introduced to British Columbia as a contaminant in an unsorted or poorly sorted shipment of Largemouth Bass. The electrofishing sample from Silvermere Lake taken on 21 July 2005 contained the single Yellow Bullhead, 1 Brown Bullhead, 5 Pumpkinseeds (*Lepomis gibbosus*), 28 Prickly Sculpins (*Cottus asper*), 30 Black Crappie (*Pomoxis nigromaculatus*), and 57 Largemouth Bass (*Micropterus salmoides*). Note that only one species (*Cottus asper*) in the six caught in Silvermere Lake is native to the Fraser River drainage, and that single native species made up only 23% of the catch.

The date of introduction of Brown Bullheads into British Columbia is unknown, but they were stocked in Washington from 1874 onwards, and those on Vancouver Island date back to 1906 (Carl and Guiguet 1957; Carl et al. 1967; Wydoski and Whitney 2003). According to anecdotal evidence, the initial stocking in Beaver Lake on Vancouver Island was accomplished from the window of a passing train, and these few bullheads were from an aquarium displayed in a local restaurant (Carl and Guiguet 1957; Carl et al. 1967). Langford Lake and other lakes were stocked soon after, from the Beaver Lake population. It is possible that Black Bullheads were a contaminant in the early stocks of Brown Bullhead since the two species can be difficult to differentiate, especially when young (Becker 1983; Lever 1996). However, if present, Black Bullheads failed to reproduce and were extirpated while the Brown Bullhead survived on Vancouver Island.

Bullhead catfish have not spread far in British Columbia because the warm, eutrophic conditions they require are found only in lakes and ponds of southern Vancouver Island, the Fraser River Delta, and the southern portions of the Columbia River drainage in this province. Where they have been introduced, bullheads are reputed to be effective nest predators, and have been implicated in the elimination of Threespine Stickleback (*Gasterosteus aculeatus*) populations in smaller lakes along the coast (McPhail and Lindsey 1986). Male stickleback cannot repel intruding adult bullheads, and in one lake near Mission, a large population of sticklebacks went extinct only two years after bullheads were introduced (McPhail and Lindsey 1986; Wydoski and Whitney 2003). The addition of the Yellow Bullhead (*Ameiurus natalis*) to

FIGURE 4. Photographs of (A) the live Yellow Bullhead (*Ameiurus natalis*) just after capture, and (B) the same specimen once preserved (RBCM 005-079-001); ruler in (B) is in centimetres.

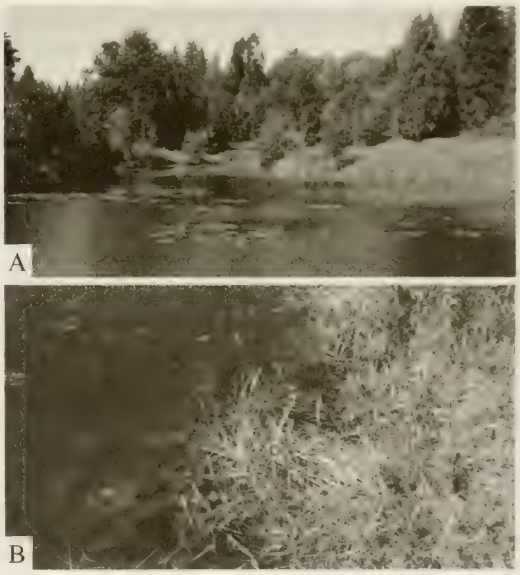

FIGURE 5. The southeast bay on Silvermere Lake just north of Highway 7 (A) and detail of shoreline habitat (B) where the Yellow Bullhead was collected.

British Columbia's aquatic biota is not to be celebrated, and probably represents one more case of a contaminant species accidentally released with a transplant of game fish.

Acknowledgments

Initial information on the pacu from Green lake was provided by Craig Wightman, Fish Biologist, and Randy Dolighan, Ecosystem Biologist, both with the Ministry of Water, Land and Air Protection, Environmental Stewardship Division, 2080-A Labieux Road, Nanaimo V9T 6J9. Mike deLaronde, Conservation Officer, Industrial Investigations, 2080-A Labieux Road, Nanaimo V9T 6J9, provided the photograph of the pacu from Green Lake. Thanks to Kelly Sendall for information on the *Panaque* in RBCM collections and changing the data record to reflect the new and correct species identity. Financial support for field work in 2005 was provided by the Royal British Columbia Museum. Ken Stewart (University of Manitoba, Department of Zoology), and James Cosgrove (Royal BC Museum, Department of Natural History), and two anonymous individuals reviewed and greatly improved an earlier, rushed draft of this manuscript; their comments and suggestions are greatly appreciated.

Regional Variation in *Amelanchier* in the Whitewood area of Southeastern Saskatchewan and the First Saskatchewan Records of *Amelanchier sanguinea*

Paul M. Catling and G. Mitrow

Agriculture and Agri-Food Canada, Environmental Health, Biodiversity, Saunders Building, Central Experimental Farm, Ottawa, Ontario K1A 0C6 Canada; e-mail: catlingp@agr.gc.ca

Catling, Paul M., and G. Mitrow. 2006. Regional variation in *Amelanchier* in the Whitewood area of southeastern Saskatchewan and the first Saskatchewan records of *Amelanchier sanguinea*. Canadian Field-Naturalist 120(4): 428–432.

Based on measurements and evaluation of 111 specimens from 51 localities in the Whitewood area of southeastern Saskatchewan, most *Amelanchier alnifolia* from the prairie parkland is represented by short, stoloniferous shrubs, less than 2 m tall with 5 – 100+ stems. In the Moose Mountain area, *A. alnifolia* is represented by shrubs that are taller, sometimes to 7 m, not stoloniferous and usually having fewer than five stems. Although many of these plants have the inflorescence characteristics of *A. alnifolia*, some are referable to the eastern *A. sanguinea*, not previously reported from southeastern Saskatchewan. Such plants appear to be confined to the wooded environment of Moose Mountain. *Amelanchier alnifolia* is not as clearly differentiated by habit or leaf tip characteristics as the literature suggests. Inflorescence characteristics, habit and actual genetic variation may be associated with biogeographic patterns, especially historically wooded islands within the prairie ecozone. These patterns are an important consideration in classification studies and in protecting and utilizing *Amelanchier* germplasm.

Key Words: Juneberry, Serviceberry, Shadbush, Saskatoon, *Amelanchier alnifolia*, *A. sanguinea,* status, biogeophaphic variation, hybrid, agamospermy, Moose Mountain, Saskatchewan.

At least three species of *Amelanchier* are known to occur in the prairie region of Canada. *Amelanchier alnifolia* (Nutt.) Nutt. is widespread, *Amelanchier florida* Lindl. is confined to ravines in the Cypress Hills (reported by some authors and not by others) and *A. sanguinea* (Pursh) DC. occurs in southeastern Manitoba (e.g. Boivin 1967; Looman 1979). Reports of *A. sanguinea* from the northern Great Plains (Stephenson 1973; McGregor et al. 1977) are based on *A. humilis* Wieg. (McGregor et al. 1986), whereas Boivin's (1967) report of *A. sanguinea* in southeastern Manitoba may be based on material of both *A. sanguinea* and *A. humilis* since he combined the latter with the former and both occur in the general region and in northern Minnesota (Nielsen 1939; Jones 1946).

In general, flowering material of *A. sanguinea* is distinguished from *A. alnifolia* by having flowering pedicels more than 15 mm long instead of less than 10 mm long (Boivin 1967; Cinq-Mars 1971; Gleason and Cronquist 1991) and petals 11-22 mm long instead of 6-10 mm long (e.g., Jones 1946). In addition, *A. sanguinea* is characterized as a tree with oblong, pointed leaves and *A. alnifolia* is generally characterized as a stoloniferous shrub with truncate or rounded leaves (e.g., Nielsen 1939; Jones 1946; Fernald 1950). *Amelanchier humilis* is distinguished from *A. alnifolia* by its acute or obtuse instead of truncate or broadly rounded leaves (Cinq-Mars 1971; McGregor et al. 1986). McGregor et al. (1986) have indicated that it is difficult to separate *A. alnifolia* and *A. humilis* in the northern Great Plains and they have suggested that some colonies "appear as hybrid swarms and the two could easily be considered as variants of one species." The concept of including *A. humilis* with *A. alnifolia* is not new since it was the basis for McKay's (1973, 1975, 1976) transfer of Nielsen's *A. humilis* var. *compacta* to *A. alnifolia* (*A. alnifolia* var. *compacta* (Nielsen) McKay).

During a survey of *Amelanchier* in the Whitewood and Moose Mountain areas of southeastern Saskatchewan in early June 2005, it appeared that plants in the prairie-parkland region (ecodistricts 752, 756, 760, Agriculture and Agri-Food Canada 1995) differed from those on the elevated Moose Mountain plateau (ecodistrict 761) which was forested in presettlement times (Catling and Kostiuk 2006). This rolling plateau, almost 400 km^2 in extent with numerous lakes and well-drained wooded slopes with aspen (*Populus*) and birch *(Betula)* forest, is 100 – 150 m above the surrounding plains.

The objective of the work reported here was to document the variation and to provide a context for the first report of *Amelanchier sanguinea* in Saskatchewan. This information is relevant to systematic studies of *Amelanchier* and is also of interest with regard to the protection of native *Amelanchier* germplasm. Although Saskatoon (*Amelanchier alnifolia*) is one of Canada's fastest growing native crops, its variation is not well understood and its domestication has yet to take advantage of the full range of variability available (Catling and Small 2003).

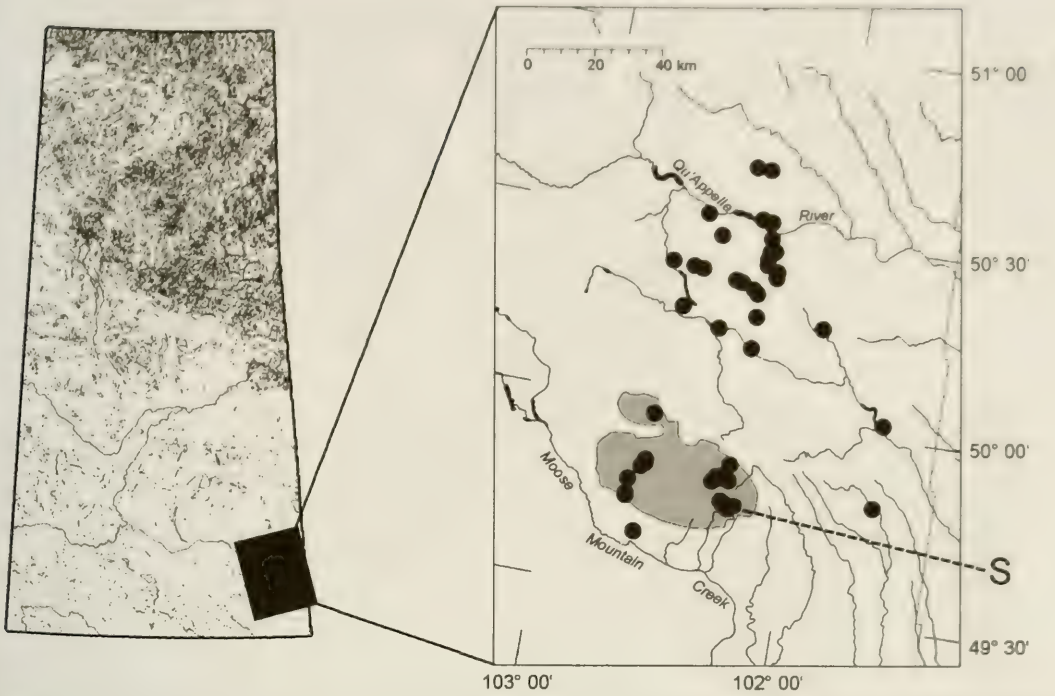

FIGURE 1. Saskatchewan (left) showing location of Whitewood study area (right). Collection localities of *Amelanchier* used in the study are indicated by dots. The Moose Mountain ecodistrict is shaded. The collection site of *A. sanguinea* is indicated by "S" and dashed line connected to the dot.

Methods

In June 2005, during late flowering, 111 specimens of *Amelanchier* were collected and measured from 51 sites in the Whitewood – Moose Mountain area of southeastern Saskatchewan (Figure 1). No more than five specimens were collected at each site and sites are defined as at least 0.1 km apart. Specimens were selected to represent the extremes of variation present at a site. For each specimen, lengths of lowest pedicel in an inflorescence of average size, average petal length in lowest flower in the inflorescence, average sepal length in lowest flower in the inflorescence, the plant habit (stoloniferous or not, height, number of stems), leaf pubescence (scale 1-4, 1 = glabrous, 4 = densely pubescent) and shape of the tip of a larger leaf (scale 1-5 with 1 = truncate, 5 = pointed). Stoloniferous shrubs were defined as having more than 6 separated stems and being less than 2 m in height. Non-stoloniferous shrubs were defined as having 5 or fewer stems together and exceeding 2 m in height.

The data were analysed using Principal Components Analysis (PCA), regression and histograms. PCA reduced dimensionality of six characters (Table 1), to two allowing for an evaluation of grouping and indication of pattern of variation. Histograms evaluated pedicel length with respect to habitat for different ecodistricts. F-ratios based on the comparison of the mean square variance of the regression model to the mean square of the residual indicated relationship and significance of individual characters noted above. Statgraphics software (www. statgraphics.com) was used to perform all the statistical analyses.

Results and Discussion

On the PCA plot (Figure 2) that reduces the dimensionality of six characters, the first two components account for 32.53% and 25.75% of the sample variation and the third and fourth account for 16.90% and 11.68%, respectively. On the first component, pedicel length, sepal length and height are heavily weighted whereas on the second component, leaf tip and leaf shape are heavily weighted. Leaf pubescence was not heavily weighted on either of the first two components. With a cumulative 58.28% of the sample variation accounted for in the diagram, the plot is marginally useful as an indication of potential groups, and groups are unclear. However, the plants from historically wooded Moose Mountain area occupy a specific part of the dispersion suggesting a different pattern of morphological variation from that represented elsewhere in the region.

The plants from Moose Mountain tend to have longer pedicels, and they are mostly non-stoloniferous (Figure 3). Variation in leaf tip shape, overall leaf shape, leaf pubescence and the inflorescence characters is extensive. Most plants on Moose Mountain that are presumably *A. sanguinea* on the basis of height and non-stoloniferous habit have to be treated as *A. alni-*

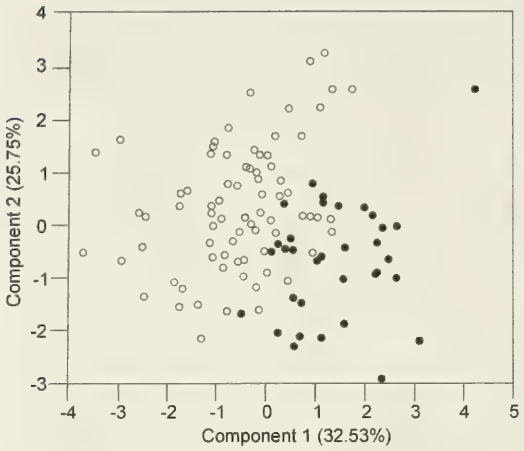

FIGURE 2. Plot of 111 specimens used in the study on the first two principal components derived from correllation among six morphological characters. The specimens from Moose Mountain are shown with solid dots and these occupy a specific portion of the dispersion suggesting distinctive variation within this region.

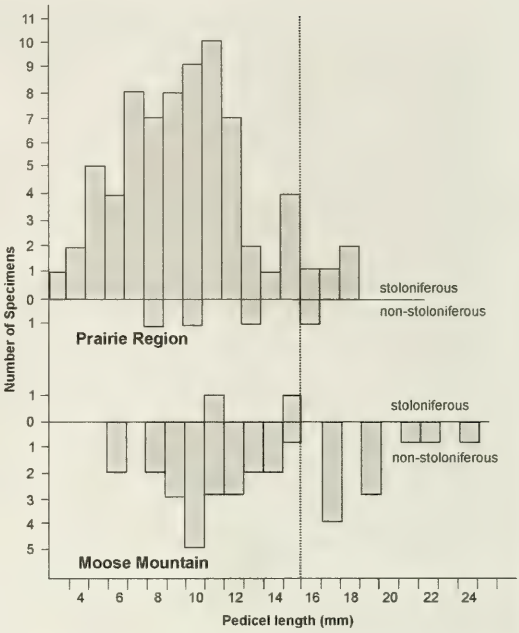

FIGURE 3. Histograms showing pedicel lengths and growth habits for specimens of *Amelanchier* from the prairie region and the Moose Mountain region of southeastern Saskatchewan.

folia on the basis of pedicels less than 15 mm long and petals less than 10 mm long. The ten plants potentially referable to *A. sanguinea* on the basis of pedicels over 15 mm (Figure 3) had leaves with variable tips. For example five shrubs had more or less truncate leaves, four had most leaves broadly rounded and two had many pointed leaves. Leaf shapes also varied. Eight of these are moderately pubescent but two are more or less glabrous. All of these ten had petals over 9 mm but under 12 mm long. The two specimens accepted as *A. sanguinea* (e.g., Figure 4 left) had pedicels 17 mm, petals 11-12 mm, pointed, moderately pubescent, oblong leaves. These two plants were distinctive in blooming later than other plants nearby that possessed fewer *A. sanguinea* characteristics. The specimen label data for these are: SASKATCHEWAN: Moose Mountain: White Bear Lake, 49.7550°N, 102.2565°W, 8 June 2005, *P. M. Catling 05-27, B. Kostiuk* (DAO); Good Bird Point, White Bear Lake, 49.7639°N, 102.2328°W, 6 June 2005, *P. M. Catling 05-16, B. Kostiuk* (DAO). *Amelanchier sanguinea* has not been reported previously from Saskatchewan (Harms 2003).

Amelanchier alnifolia from the prairie parkland is represented mostly by short, stoloniferous shrubs, less than 2 m tall with 5–100+ stems, but taller, non-stoloniferous shrubs also occur in poplar groves. The smaller stoloniferous plants often have distinctively short and dense racemes with pedicels little if at all longer than the petals (Figure 4, right). The leaves may be truncate or more or less pointed.

The regressions indicated that pedicel length had the most significant relationships with other characteristics and was significantly correlated with ecodistrict (Table 1). Sepal length was also significantly correlated with other characters, but was not significantly associated with leaf tip which is regarded as a significant character for distinguishing *A. alnifolia* by some authors (see above). In overall addition of significance values, pedicel length was three time more significant than sepal length. Futhermore, sepals are more often damaged or shrunken (as in fruit) whereas pedicels are more often intact. This represents the first quantitative support for the use of pedicel length in defining taxa. Leaf shape was only highly correlated with leaf tip and was not significantly related to ecodistrict suggesting limited use in defining taxa. These suggestions are based on the operational concept of taxa being defined by a number of correlated morphological characters and by some ecological discreteness. Thus the more recently defined (see above) characters are supported and these are included in the following key which will differentiate the four species known from the prairie provinces.

1a. Pedicels short, less than 10 mm long; petals 4-10 mm long; mostly stoloniferous shrubs 2
2a. Leaves glabrous or sparsely tomentose at flowering, truncate or broadly rounded . . . *A. alnifolia*
2b. Leaves persistently pubescent at flowering, obtuse to acute . . . . . *A. humilis*
1b. Pedicels longer, over 15 mm long; petals 11-22 mm long; non-stoloniferous shrubs 3
3a. Leaves glabrous at flowering . . . . . *A. florida*
3b. Leaves more or less tomentose at flowering . . . . . *A. sanguinea*

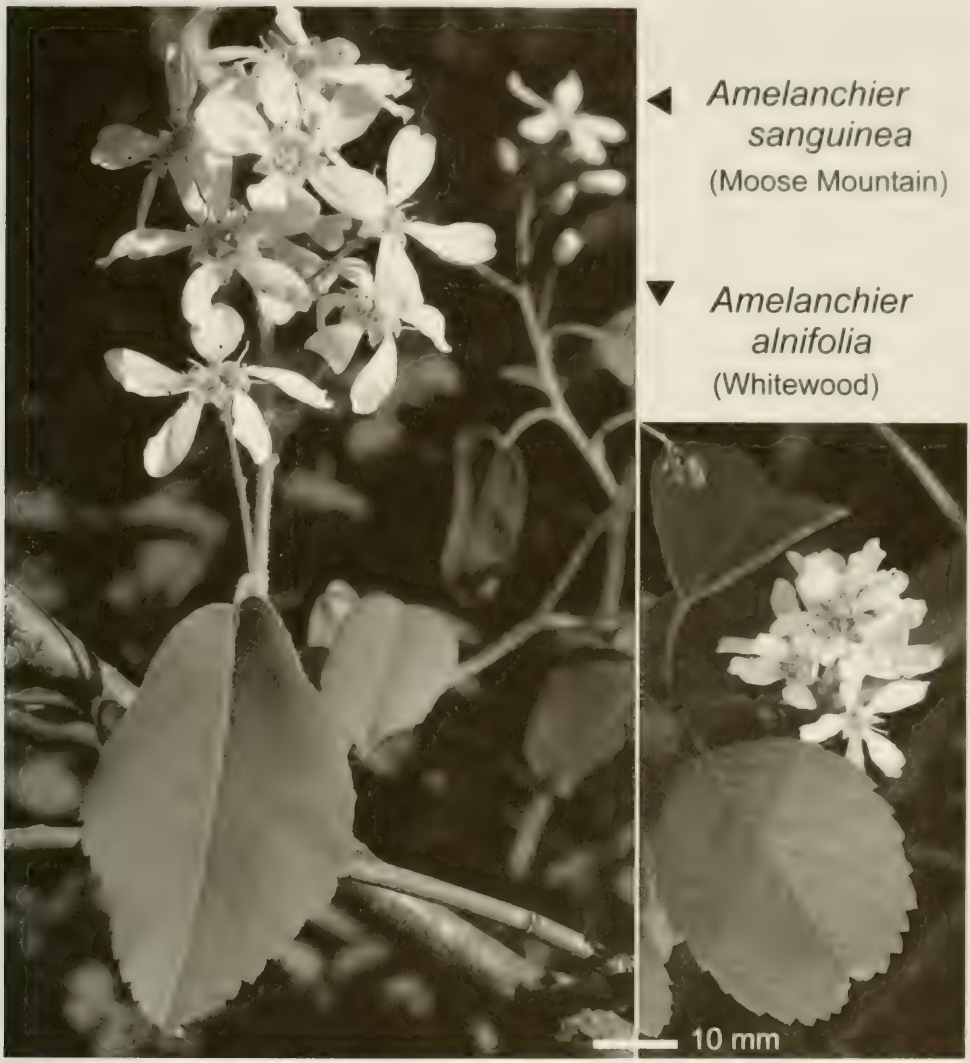

FIGURE 4. *Amelanchier sanguinea* from Moose Mountain, near White Bear Lake (left) with relatively long pedicels and open inflorescence and pointed oblong leaves. *Amelanchier alnifolia* (right) from relict prairie along the railway west of Whitewood with a dense infloresence, relatively short pedicels and a truncate and rounded leaf.

It appears that *A. sanguinea* is uncommon in the Moose Mountain upland whereas hybrids with *A. alnifolia* that have inflorescence features of *A. alnifolia,* and other characters in various combinations, are frequent. In many cases the difficulty in identifying *Amelanchier* material has been attributed to hybridization, introgression and agamospermy (e.g., Robinson 1982; Campbell and Wright 1996) but this aspect has yet to be investigated in the prairie region. There is much more variation in plants referred to *A. alnifolia* than was previously suspected. This variability appears to have a pattern to some extent associated with biogeographic boundaries. The correlation with biogeography may provide a useful basis for the utilization and protection of germplasm and it may also provide a means of determining groups and optimal characters in future taxonomic studies.

It is possible that differentiation of *Amelanchier* related to forested or unforested habitats in central North America has been going on for many thousands of years and that this phenomenon spread into southeastern Saskatchewan from the south following melting of the continental glacier about 10 000 years ago. Plants corresponding to *Amelanchier sanguinea* may have been present in the Moose Mountain area with early postglacial poplar- or spruce (*Picea*) dominated

TABLE 1. Significance of F-ratios from simple regression for seven characteristics of *Amelanchier* in the Whitewood area of southeastern Saskatchewan. A significant relationship is defined as below 0.05 and is shown with boldface.

Character	(1)	(2)	(3)	(4)	(5)	(6)	(7)
(1) pedicel length	–						
(2) leaf tip	0.0679	–					
(3) leaf shape (l/w)	0.1463	**0.0000**	–				
(4) leaf pubescence	0.3619	0.8416	0.7942	–			
(5) sepal length	**0.0009**	0.6304	0.0675	0.9942	–		
(6) height	**0.0000**	0.3648	0.7270	**0.0003**	**0.0000**	–	
(7) ecodistrict	**0.0000**	0.3938	0.2410	0.0675	**0.0000**	**0.0000**	–

forests that were widespread for a short period about 10 000 years ago, prior to replacement by persisting grassland (e.g., Ritchie 1976), which isolated the forested uplands. Alternatively these plants could have invaded after the Moose Mountain forest was isolated. Consumption of seeds by berry-eating birds would allow long-distance dispersal between forest patches. The recent discovery is not an indication of very recent arrival (although that is a possibility); rather it suggests that the classification and ecology of *Amelanchier* on the Canadian prairies is not well understood and requires much more study.

Acknowledgments

Useful reviews were provided by W. J. Cody and J. Cayouette. For extensive help in the field, we are indebted to B. Kostiuk. Staff of Moose Mountain Park provided useful information.

Observations on the Nesting of the Northern Hawk Owl, *Surnia ulula*, near Timmins and Iroquois Falls, Northeastern Ontario, in 2001

MICHAEL PATRIKEEV

3 Helen Street, Dundas, Ontario L9H 1N2 Canada; e-mail: mpatrikeev@hotmail.com

Patrikeev, Michael. 2006. Observations on the nesting of the Northern Hawk Owl, *Surnia ulula*, near Timmins and Iroquois Falls, northeastern Ontario, in 2001. Canadian Field-Naturalist 120(4): 433–437.

Three breeding pairs of Northern Hawk Owls were observed in northeastern Ontario in the vicinity of Timmins and Iroquois Falls in 2001, and two nests and a brood were recorded. The young from one nest fledged prematurely (likely due to a storm) and the another nest probably failed. Four other territorial pairs were observed. Notes on nest sites, feeding and nest attendance were taken.

Key Words: Northern Hawk Owl, *Surnia ulula*, nesting, northeastern Ontario, clearcuts.

The distribution and biology of the Northern Hawk Owl (*Surnia ulula*) have not been well documented in North America with fewer than 20 papers published on this species by the mid-1990s (Duncan and Duncan 1998). In Ontario, the Northern Hawk Owl breeds in the boreal forest zone south to latitude 48°, with occasional records south to Parry Sound, Algonquin Provincial Park, and Ottawa (Peck and James 1983; Weir 1987). During the first Ontario Breeding Bird Atlas (OBBA), 1981-1985, the Northern Hawk Owl was found in 0.8% of surveyed 10 × 10 km squares, and during the second OBBA (2001-2004) in 4.2% of squares (OBBA, unpublished data, courtesy of A. Heagy, Bird Studies Canada). This increase in records likely resulted from better access in the boreal forest owing to the extensive network of forest access roads built in the 1990s and early 2000s, more effort directed to northern areas, and an influx of Northern Hawk Owls in northwestern (Escott 2002) and northeastern Ontario (personal observation). Only 25 nests were reported to the Ontario Nest Record Scheme by 2004, with 21 nests from northwestern Ontario (Escott 2002; G. Peck, personal communication).

In May 2001, two nests and three additional Northern Hawk Owl territories were recorded in the drainages of the North Driftwood and Mattagami rivers in Crawford Township north of Timmins, Ontario (48°49'48"N, 081°27'14"W). In June, a pair with a brood and another territory were found in the drainage of Shallow River in Wilkie Township, the City of Iroquois Falls (48°32'15"N, 080°27'59"W). All sites were in Cochrane District (Figure 1).

The nests found in Crawford Township (about 1.3 km apart) were in small stands of medium age mixed forest with low density of living trees and many tall hardwood snags, and surrounded by clearcuts. The stands consisted mostly of Black Spruce (*Picea mariana*) and Balsam Fir (*Abies balsamea*), with fewer poplars (*Populus*), American Larch (*Larix laricina*), Jack Pine (*Pinus banksiana*), and Paper Birch (*Betula papyrifera*). A large number of snags likely indicated past herbicide treatment of deciduous trees to allow for more rapid regeneration of coniferous species. In Wilkie Township, a pair with brood occurred in a small stand of poplars defoliated by Forest Tent Caterpillars (*Malacosoma disstria*) and also adjacent to sizable clearcuts. Other territorial Hawk Owls hunted in wetlands (treed fen), burned areas and overgrown clearings. The nests found in 2001 were in cavities at the top of poplar snags, at 7 and 8.5 m above the ground (Number 1 and 2, respectively). Nest Number 1 was in a shallow cavity open from the above, and Number 2 in a cavity open on one side (Figures 2 and 3). Nest Number 1 was near the stand edge, close to a clearcut, and Number 2 was ca. 10 m away from a moderately used road. The nesting site in Wilkie Township was about 20 m from a forest access road.

Nest sites were visited between 19 May and 25 June, and nest Number 1 was observed from an elevated blind on 30 May, 11 and 12 June between 10:45 and 20:30 hours (for a total of 14.5 hours), with 10× binoculars, and a photographic camera fitted with 500 mm lens. It was assumed that the larger owl that spent most of the time on the nest, and cared for the young was female, and the smaller owl that brought food and made territorial calls was male [according to Duncan and Duncan (1998) incubation and brooding of the young in this species is by the female only].

In nest Number 1 incubation lasted to at least 30 May (incubation was presumed because the female remained seated on the nest, changing her position infrequently and was not seen feeding when food was delivered). At least two young in gray down (presumed to be ca. 7 days old) were seen raising heads in that nest on 11-12 June, but the nest was empty when examined on 25 June. High winds with gusts reaching 89 km/hour resulting from the aftermath of Tropical Storm Allison reached the area on 19 June (Environment Canada website: http://www.climate.weatheroffice.ec. gc.ca), and the young might have fledged prematurely because of

FIGURE 1. Location of the 2001 Northern Hawk Owl nesting records from Cochrane District.

wind. At least one young begged for food on 25 June in the nest vicinity, but it could not be located in the thick growth of spruce and Balsam Fir. The young were likely only ca. 14-18 days old when the high winds struck. Elsewhere in North America, the young leave the nest when 20-30 days old (Kertell 1986; Lane and Duncan 1987).

The fate of nest Number 2 was unknown. The female was in the nest cavity and presumably incubating up to 28 May. On 29 May the female was sitting in an incubating posture higher than previously, suggesting that the young might have hatched. On 10 June, both adults were near the nest displaying aggressive behavior and uttering alarm calls, but no owls visited the nest between 07:45 and 10:00 hrs on the following day, 11 June (when observed from a blind), and no young called. Hawk Owls were also observed not far from nest Number 2 on 25 and 30 June, but no alarm or begging calls were heard. Escott (2002) reported a nest failure near a busy logging road in Thunder Bay District, but traffic near this nest was moderate at the most and unlikely had anything to do with the nest's fate.

In the Shallow River Valley breeding area one fledged young was observed on 13 June, and four fledglings at the same site on 23 June. The largest of these young was completely feathered on 23 June when the other three still had some down on heads and bodies (Figure 4). One flew ca. 20 m when approached thus suggesting that it was at least 30 days old (see Duncan and Duncan 1998).

Some information on nesting and feeding behavior of this species was gathered while observing nest Number 1. The female from that nest never left it during several short visits 19 to 29 May, and 3.5 hours of observation on 30 May (presumably incubating). The male was calling (advertising call, Mikkola 1983) from perches in the vicinity. On one occasion the incubating female also uttered an "ulululu" call very similar to advertising call of the male. After the young hatched, the female sometimes left the nest to hunt, or perched in the vicinity (up to ca. 100 m from the nest) calling for food from time to time. On 11 June, during 6 hours of observation, the female was absent from the nest for a total of 73 minutes, and on 12 June (5 hours of observation) for 71 minutes. On average, she was absent for 24 ± 21.9 minutes at a time (range 3-65 minutes, n = 6). These numbers do not include short absences when the female flew off the nest to meet the male delivering food.

During the observation period food was brought to the female between 11:20 and 20:00 hrs. On eight occasions, the male flew directly to the nest, but on 12 June two food transfers occurred outside the nest. The male never lingered, leaving the nest in ca. 10 seconds after passing food to his mate, but he often perched nearby. At nest Number 2, the male was seen deliver-

FIGURE 4. This large fledgling Northern Hawk Owl was photographed in Wilkie Township, near Iroquois Falls, on 23 June 2005. Photo by Michael Patrikeev.

ing to the nest once, and twice the food transfer took place outside the nest. Prey delivery intervals at nest Number 1 varied from 49 minutes to 3 hours and 8 minutes (on average 120.4 minutes ± 66.3 minutes, $n = 8$). These were longer than intervals between feeding of fledglings reported by Lang et al. (1991) from northern Manitoba: 48.5 min ± 34.9 SD ($n = 12$, range 10-130 min). Of 10 observed prey items 7 were Meadow Voles (*Microtus pennsylvanicus*), 1 Northern Short-tailed Shrew (*Blarina brevicauda*), and the remaining two were either small mammals or small birds. The male removed heads of some voles before bringing them to the nest, whereas other prey was delivered whole. Prey beheading was also reported by Duncan and Duncan (1998). It was unclear whether the male ate the heads, as no cranial or dental material was found in pellets cast in the vicinity of the nest, although on one occasion, the female swallowed a prey item whole, head first. The female fed the young from beak to beak or held a partially skinned vole over the young's heads allowing them to tear at the carcass (Figure 5).

In southern Cochrane District in 2001, Northern Hawk Owls nested in recent cutovers possibly treated with herbicides to stress regeneration of deciduous trees. These owls are known to utilize clearcuts for nesting (Duncan and Duncan 1998), and they showed preference for chemically treated clearcuts in northwestern Ontario during their influx in the early 2000s (Escott 2002). Clearcuts with tall snags and few shrubs possibly mimic recently burned areas and other open habitats preferred by this species in its core range further north, and provide both nesting sites and open hunting habitat (Duncan and Duncan 1998). Populations of some prey species (e.g., Meadow Vole) may be more numerous in recent cutovers (Sullivan et al. 2004). Clear-cutting in northeastern Ontario will likely create more ephemeral nesting habitat for this species providing that groups of trees and snags remain after cutting.

Acknowledgments

I thank James R. Duncan (Manitoba Conservation, Winnipeg, Manitoba), Jack C. Eitniear (San Antonio, Texas), A. J. Erskine, and an anonymous reviewer for useful comments and suggestions regarding the manuscript, George Peck (Royal Ontario Museum) for providing me with unpublished Northern Hawk Owl nest records, Audrey Heagy (Bird Studies Canada, Port Rowan, Ontario) for assisting in the review of the literature and helping to obtain unpublished OBBA information, and Jay Malcolm (University of Toronto, Ontario) for information on small mammals and clearcuts.

Bertrand, A.-S., S. Kenn, D. Gallant, E. Tremblay, L. Vasseur, and R. Wissink. 2006. MtDNA analyses on hair samples confirm Cougar, *Puma concolor,* presence in southern New Brunswick, eastern Canada. Canadian Field-Naturalist 120(4): 438–442.

For the last 40 years, the presence of Cougars (*Puma concolor*) in eastern Canada has been highly controversial. The purpose of this study was to collect physical evidence of Cougars using a passive detection method. Baited hair-traps combined with camera-traps were installed in New Brunswick and Nova Scotia, Canada. DNA analyses on two hair samples confirmed that the species was present in southern New Brunswick in 2003. A footprint photographed after an observation of a Cougar by reliable observers was examined by experts and was consistent with a Cougar footprint. Additional data are required to determine the status of Cougars in the northeastern part of its historical range.

Key Words: Cougar, *Puma concolor*, hair-traps, camera-traps, physical evidence, mtDNA analyses, tracks, eastern Canada.

Historically, the Cougar (*Puma concolor*) was distributed all across the American continent, from southeastern Alaska to southern Argentina and Chile (Parker 1998). It was the most widely distributed terrestrial mammal in the western hemisphere (Godin 1977). The subspecies referred to as Eastern Cougar (*Puma concolor couguar*) was known to occur in Nova Scotia [NS], New Brunswick [NB], Quebec [QC], Michigan, Tennessee and South Carolina (Goldman 1946). While 32 subspecies were initially listed by Goldman (1946), a recent DNA study by Culver et al. (2000) showed that only six genetically distinguishable subspecies are now believed to occur in the western hemisphere, with only one for North America; i.e., *P. c. couguar*. Populations in northeastern America drastically declined at the beginning of the last century (Parker 1998). Weaver et al. (1996) argued that conflicts for resources and land uses may be the main causes of most Cougar extirpation in North America. Previous studies across North America have indicated that road density, urbanization, agriculture and timber harvesting may also limit Cougar expansion (van Dyke et al. 1986; Maehr et al. 2002; Taylor et al. 2002; Dickson et al. 2005).

The status of the Cougar in eastern North America has always been a highly controversial topic (Cumberland and Dempsey 1994). Due to the secretive habits of this species and the highly fragmented regions where few scattered individuals possibly remain, solid evidence (i.e., a dead animal, DNA collected from scat or hair, a clear photograph or indisputable confirmation of authenticated tracks) is difficult to collect, making decision and species-at-risk designation difficult. Provincially, Cougars are listed as undetermined in NS, and endangered in NB. At the federal level, the status of the eastern cougar population was changed from endangered to data deficient in 1998 (Scott 1998*). No reliable estimate of the number of Eastern Cougars has ever been made because authentic, scientifically-based evidence is lacking (Cumberland and Dempsey 1994). However, numerous credible sightings and physical evidences have since then reopened the Eastern Cougar debate. An extensive review carried out by the Committee on the Status of Endangered Wildlife in Canada [COSEWIC] in 1978 leaves little doubt as to the historical presence of Cougars in eastern Canada (van Zyll de Jong and van Ingen 1978*). Today, the major concern of provincial wildlife agencies is whether the reported animals are natives or feral escaped or released captives (Scott 1998*).

While extensive, logistically demanding fieldwork is usually required to search for such a wide-ranging species, this paper focuses on new data obtained for NB through non-invasive detection methods (i.e., baited hair-trap and camera-trap).

Material and Methods

Study Areas

This project was conducted in NB and NS with 12 traps set up in three national parks, i.e., Fundy National Park of Canada [FNP], Kouchibouguac National Park of Canada [KNP] in NB, and Cape Breton Highlands National Park of Canada [CBHNP] in NS. Conservation units being the largest wilderness areas available, they are more likely to shelter wide-ranging top predators than urban or agricultural lands. Two additional

FIGURE 1. Baited hair-trap (n = 14) locations (triangles) in New Brunswick and Nova Scotia, eastern Canada.

traps were installed in remote areas in the Miramichi region (northeastern NB) because sightings from reliable observers (biologists and trappers) were frequently reported to provincial wildlife agents. All traps were located according to the most recent credible sighting report or physical evidence (Figure 1). Four traps were set up in FNP in forested habitats on the rolling upland plateau. FNP (205.9 km^2) is characteristic of the Maritime Acadian Highlands region and is part of the Appalachian Mountain range (Woodley et al. 1998). Three other traps were installed in KNP (239.2 km^2) in northeastern NB. Two traps were installed in coniferous stands, one in a relatively remote area near Black River in KNP's central region, and the other, less than 1 km from human habitations along the southeastern boundary of the park. The last KNP trap was installed in a hilly mixed wood stand 3 along the Major Kollock creek. Finally, five traps were installed in CBHNP (948.0 km^2), the largest protected wilderness area in NS, protecting 20% of northern Cape Breton. Traps were installed based on recent convincing Cougar sightings in deciduous, mixed wood and dead conifer forests. All trap locations had a closed canopy, an important amount of coarse woody debris or a thick leaf litter, and were close to water sources.

Non-invasive detection techniques

Field work began during the fall of 2003. The passive detection methods used entail collecting hairs, tracks, and scats in a non-invasive manner. Baited hair-traps (Figure 2), consisting of 2-m-high posts surrounded by 3 × 3 m^2 squared enclosures, were installed in areas where credible sightings had recently been reported (Figure 1). Two barbed wire strands were stretched around the wooden posts delimiting the enclosure, at 45 cm and 75 cm from the ground respectively. This was intended to catch hair as the animal enters the enclosure, attracted by the species-specific lure. Dripping lure (i.e., Cougar urine obtained from captives, sex unknown) was hung inside the perforated central post and fresh lure was added every month.

In 2004, in an attempt to get photographic records of animals entering the enclosure, we equipped each station with a camera-trap unit which consists of either a 35-mm or a digital camera triggered by an infrared motion sensor. Each camera was fastened to a tree near the scent post, at a height of 1.8 m (Figure 2). Any motion up to 7 m away within an angle of 120 degrees activated the camera. Traps were checked year-round every 4-5 weeks.

DNA analyses

Samples were submitted to a sequence-based analysis of 16S mitochondrial DNA (mtDNA; Johnson and O'Brien 1997). DNA was extracted from hair samples using QIAGEN DNeasy Tissue kits. In order to determine whether DNA samples were from felid or other mammal species (i.e., felids, canids, cervids, 4 mustelids, procyonids, and ursids), 300 base pairs of 16S mtDNA were amplified using Polymerase Chain Reaction (PCR).

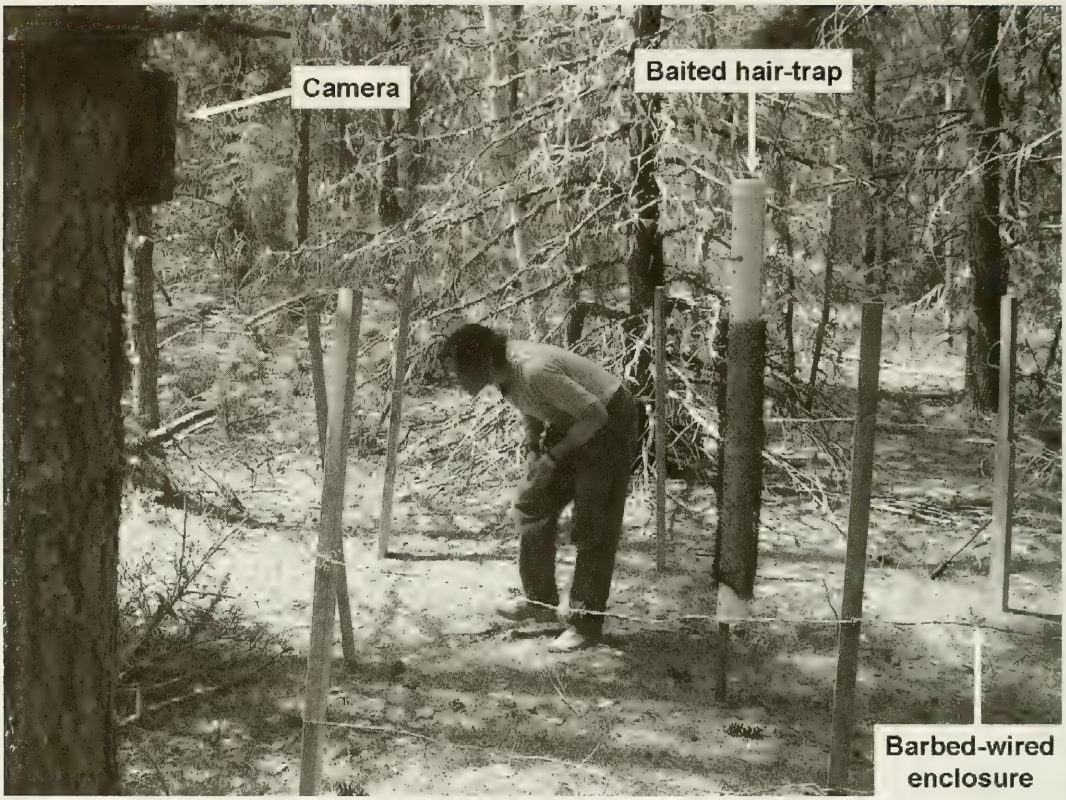

FIGURE 2: Experimental design for Cougar detection, a passive method combining a baited hair-trap (central post and barbed-wired enclosure) protocol and a camera-trap (upper left corner, strapped on a tree).

A volume of 15μL contained 100-500 ng template DNA, 1× reaction buffer, 1.5 mmol (millimoles) $MgCl_2$, 0.3 mmol each primer, 250 mmol dNTPs and 1 U *Taq* polymerase. After initial incubation at 94°C for 2 minutes, 40 cycles of PCR were performed at 94°C for 1 minute, 53°C for 1.5 minutes, 72°C for 1.5 minutes, and 72°C for 10 minutes. Results were then visualized on a 2.0% agarose gel and compared to 20 species from the six families cited above. A second amplification of 600 bp of a specific region of the 16S mtDNA was then conducted according to the protocol detailed by Mills et al. (2000). Restriction enzymes *Hae*III, *Hpa*II, and *Rsa*I then digested PCR products at 37°C during 12 hours, and results were visualized on 2.5% agarose gel. Since restriction enzymes produce species-specific patterns, it was then possible to distinguish Cougar from other felid species.

Results

Baited hair traps

A total of 207 samples was collected from hair traps (Table 1). MtDNA analyses conducted on hair samples collected in 2003 revealed that two samples collected in FNP were Cougar hair. The first hair sample was found near the main road entering the park (i.e., Kinnie Brook), in a young Red Spruce (*Picea rubens*) and Balsam Fir (*Abies balsamea*) stand (6 to 12 m high, canopy closure of 70%). Ground cover mostly consisted of *Sphagnum* spp. and Bunchberry (*Cornus canadensis*). The other hair sample was found in the northern area of the park, along an old logging trail (i.e., Big Dam trail) relatively overgrown with Red Spruce, Balsam Fir and birch (*Betula* spp.). In this case, trees were taller (12-20 m) but canopy closure was only 40-50%. A 6-m-high understory composed of Balsam Fir, Red Spruce and White Birch (*Betula papyrifera*) allowed no ground cover other than birch leaves.

TABLE 1. Number of hair samples collected per location and per year for 2003-2006.

Location	Sampling periods			
	2003	2004	2005	2006
KNP	0	6	15	7
FNP	29	34	49	23
CBHNP	1	3	17	16
MIRAM	–*	–	6	1
Total	30	43	87	47

*Baited hair-traps and camera-traps were installed in the Miramichi (MIRAM) area during the fall of 2004.

FIGURE 3. Footprint found west of Blackville (GPS coordinates (NAD 1983): 20N0724671; UTM 5188486), New Brunswick, Canada (22 September 2004). Picture provided by P. Boucher. Box (to left of footprint) diameter: 8.5 cm.

Further DNA sequencing revealed that the two hair samples came from two distinct animals, i.e., a North American specimen and a South American specimen. Camera-traps were only installed in 2004, so there is no photographic record of these two individuals. No Cougar hair or picture were collected after the cameras had been installed.

Additional Observation

Sets of tracks can also be used to identify species (van Dyke and Broke 1987; Cumberland and Dempsey 1994). A footprint (Figure 3) was photographed in 2004 by three reliable observers in Blackville (southwest of Miramichi, New Brunswick) 15 minutes after they had seen the Cougar at 12:25 PM and watched it for several seconds as it was crossing a dirt road 45 m from them. This track was examined by experts and declared not to be of a Coyote (F. Scott and P. G. Crawshaw Jr., personal communication).

Discussion

Cougar detection program for the Maritimes

Hair-traps and camera-traps are alternative and convenient non-invasive methods that are cost- and time-efficient techniques for animal surveys (Carbone et al. 2001). After four years of permanent cougar monitoring in the Maritimes, the amount of field data keeps increasing. As suggested by Cardoza and Langlois (2002), it would be valuable to establish a systematic monitoring program supervised by an expert team for the Eastern Cougar population, especially for the provinces where the status of this species is indeterminate. This would allow collection of a series of undisputable physical evidence (Cardoza and Langlois 2002; Maehr et al. 2003). As mentioned by others, the probability of proving the presence of a species which has no established viable populations in a given area is almost nil (Broke and van Dyke 1985).

DNA hair analyses confirmed that two Cougars occurred in southern NB in 2003. Additional data (e.g., individual genetic haplotype) are nonetheless crucial to better understand the status of the species in this part of its range. One of the individuals detected in Fundy turned out to be a South American animal, recalling the Chilean specimen shot in Abitibi, Québec, in May 1992 (Jolicoeur et al. 2006). This may indicate that a few scattered escapees from zoos or captives released by private owners remain (Stocek 1995). However, the other positive hair sample caught in the Big Dam Trail in FNP was from an animal of North American origin. This opens up a range of possibilities. In eastern North America, estimates of the number of escaped captives kept increasing during the last 30 years. In Pennsylvania for instance, McGinnis (1996) reported only 31 cougars held in captivity in 1979, among which four or five eventually escaped. Then, less than 20 years later, according to J. Seidensticker (cited in Scott 1998*), there was an increase of 640% in the number of licensed private Cougar owners. This dramatic increase in the number of captive individuals probably suggests many more escapees of North and South American origins. Further DNA identifications will enable researchers to shed more light on this question. The fact that cougars are efficient colonizers (Nero and Wrigley 1977) with large home ranges (Seidenticker et al. 1973) ensures that the debate about the potential presence of animals in eastern Canada continues. Reported cougars may be transients, escapees or members of a remnant population, but they could act as dispersers for the (re)establishment of viable populations in eastern Canada (Scott 1998*; Maehr et al. 2002). The

determination of these cats' origin should help define the protection status they deserve.

The Leech *Haemopis lateromaculata* (Hirudinea: Haemopidae): Its North America Distribution and Additional Notes on Species Description

Peter Hovingh

721 Second Avenue, Salt Lake City, Utah 84103 USA; e-mail: phovingh@xmission.com

Hovingh, Peter. 2006. The leech *Haemopis lateromaculata* (Hirudinea: Haemopidae): Its North American distribution and additional notes on species description. Canadian Field-Naturalist 120(4): 443–451.

The geographic range of *Haemopis lateromaculata* Mathers 1963 (Hirudinea: Haemopidae) is extended across North America. Its distribution in the coastal region of Alaska and British Columbia suggests a coastal Pleistocene refugia separate from the populations in the lower United States and suggests that *H. lateromaculata* and the Eurasian *H. sanguisuga* Linnaeus 1758 are sister taxa. Support of the identification and geography is based on the anatomical positions of the reproductive organs in *H. lateromaculata* and *H. marmorata* Say 1824. The variations within these species are described, noting that no specific variation was confined to a geographical region.

Key Words: leech, *Haemopis laterormaculata*, description, taxonomy, distribution, North America.

In an effort to understand the limits of leech (Hirudinea) fauna distribution in western North America, a geographical study defined by hydrological basins was undertaken and is still in progress. The report herein describes a taxonomic problem with *Haemopis marmorata* (Say 1824) in western North America, a species known to be difficult to distinguish by external characteristics from *H. grandis* (Verrill 1874) (Sawyer 1972) and *H. lateromaculata*. Four populations of *Haemopis* were found without teeth and these populations were initially identified as *H. grandis* (Hovingh 1993). Examination by dissection revealed that the penis sheaths of these populations were *H. marmorata* and that these specimens had jaws. As a result of this identification problem, the penis sheaths of all mature *Haemopis* were examined.

In examining the reproductive organs of *Haemopis*, it became apparent that *H. lateromaculata* specimens in museum collections had often been misidentified as *H. marmorata*. A study of Utah (Beck 1954) and Alaskan (Moore and Meyer 1951) *Haemopis* vouchers deposited in the United States National Museum (USNM) contained several lots identified as *H. lateromaculata*. Three lots of specimens that were collected from British Columbia and Newfoundland, two of which were identified by J. Madill as *H. lateromaculata* plus one unidentified due to poor conditions are deposited in The Canadian Museum of Nature (CMN) in Ottawa, Ontario, Canada. The two lots at CMN are the first observations of *H. lateromaculata* outside of the type localities of Minnesota and Iowa (Mathers 1963). A specimen from Michigan was utilized in a leech phylogenetic studies (Borda and Siddall 2004).

The reproductive organs of *Haemopis marmorata* and *H. lateromaculata* specimens collected from western North America examined are presented in this paper. Based on accurate diagnosis of the species, the external characteristics (pigmentation patterns) were determined to distinguish these two species from one another. The results herein describe the geographical distribution of *H. lateromaculata*, and support some taxonomic and paleogeographic hypotheses concerning the family Haemopidae.

Methods

Specimens of *Haemopis* were collected during the last 20 years from localities in western North America. The surveys consisted of visual encounters and hand picking from the underside of stones, logs, and aquatic vegetation. The specimens were relaxed with 10% ethanol, blotted by paper towel to removed the mucous excreted from the relaxation process, fixed with 10% formalin in phosphate buffered saline between two sheets of paper towels overnight, and placed in 70% ethanol for preservation.

Identification of all large *Haemopis* specimens was determined by examining the reproductive organs through a mid-dorsal cut from the annulus with the female gonopore posteriorly approximately 20 annuli. If the penis sheath was not located with this examination, the dorsal cut was extended anteriorly for some 10 annuli. Teeth and jaws were examined by a mid-ventral cut of the lower lip. Posterior sucker width, pigmentation, and gonopore positions were noted. Small specimens were identified by pigmentation. Identifications followed original descriptions and taxonomic keys (Mathers 1963; Klemm 1985; Sawyer and Shelley 1976).

The facilities and specimens of the United States National Museum (USNM), Washington D.C. and the Canadian Museum of Nature (CMN), Ottawa, Ontario were utilized. The western specimens of Haemopidae in these collections were confirmed by dissection if the length was greater than 40 mm, and pigmentation patterns and the presence of teeth were examined. The eastern specimens of *Haemopis marmorata* were select-

ed by pigmentation with dissection on random samples. Specimens were also examined from water quality studies in Wyoming (Wyoming Department of Water Quality), now residing in the Albertson College of Idaho Orma J. Smith Museum of Natural History (ALBRCIDA), Boise, Idaho.

Taxonomic status

There is presently full acceptance of the haemopisine species (Davies 1991; Klemm 1985; Sawyer 1986). The higher classification of leech groupings, and leeches within the Annelida, is presently contentious, however. Historically, all the haemopisine species were placed in the genus *Haemopis* including the original description by Mathers (1954, 1963) of *H. kingi* Mathers 1954 and *H. lateromaculata.* Richardson (1969) revised the family Hirudinidae, established the family Haemopidae, and revised the genus classification by introducing the genera *Percymoorensis* including *P. terrestris* (Forbes 1890), *P. marmorata*, *P. lateromaculata*, and *P. kingi*), *Mollibdella grandis*, and *Bdellarogatis plumbeus* Moore 1912). He retained *Haemopis* for the Eurasian *H. sanguisuga* Linnaeus 1758. Richardson (1971) suggested that *Percymoorensis* and *Haemopis* (the Eurasian species) were associated in the subfamily Haemopinae, and that *Mollibdella* and *Bdellarogatis* were in the subfamily Mollibdellinae; he also identified a Mexican species *Percymoorensis caballeroi* Richardson 1971 in that paper.

Davies (1991); Davies and Govedich (2001); and Soós (1969) accepted the generic nomenclature of Richardson (1969) but retained the earlier familial classification of Hirudinidae. Soós (1969) expressed reservation about Richardson's classification of Hirudinidae (including Haemopidae) based on his use of type-specimens, and that "long standing genera are strongly heterogeneous in content and cannot any longer be separated one from the other entirely by single factors, or contained within single divisions in the key". Klemm (1995), Manoleli et al. (1998), and Sawyer (1986) rejected the generic nomenclatural changes of Richardson but accepted the family Haemopidae classification.

A new species, *Haemopis septagon* Sawyer and Shelley 1976, was described from specimens collected from North Carolina in eastern United States. In their description Sawyer and Shelley noted that if the classification of Richardson (1969) was accepted, *H. septagon* warranted placement in a new genus. Davies (1991) placed this species with the genus *Percymoorensis*. The uncertainty of Richardson's classification with respect to *H. kingi* and *H. lateromaculata* was revealed when Richardson (1969, 1971) stated that these two species most likely belong to a new genus. He did not examine either species but relied on Mathers (1954, 1963) for his paper (Richardson 1969). Borda and Siddall (2004) examined six species of *Haemopis* for phylogenetic studies involving anatomical characteristics, 12 S mitochondrial rDNA, 18S and 28S nuclear rDNA, and cytochrome c oxidase subunit I gene fragments. Of the 24 anatomical criteria that were utilized, 23 were common to all six species, thus not significant in determining genera or species relations. Borda and Siddall (2004) confirmed the family Haemopidae. I maintain use of the genus *Haemopis* and the family Haemopidae until additional and more conclusive phylogenetic studies have been reported for all the hemopisine species, using population samples representing the entire range of these widespread species.

Results

Distribution of *Haemopis lateromaculata* in North America

The Nearctic distribution of *Haemopis lateromaculata* is shown in Figure 1 and listed in Table 1. This distribution is based on museum specimens (USNM, ALBRCIDA, and CMN), from my (PH) collections from the geographical studies in western North America and from water quality studies in Wyoming (ALBRCIDA). Anatomical dissections distinguished *H. lateromaculata* from *H. marmorata* in western North America when the plain ventrum and plain, cream, or yellow colored lateral margins were prominent, and thus could be used to distinguish these two congeners from one another. Based on this pigmentation distinction, juvenile specimens (< 40 mm) and museum specimens in eastern North America *H. marmorata*, were examined and those with no ventral pigmentation were considered *H. lateromaculata.* Some specimens without pigmentation were dissected and the species determined. The following are the locations of *Haemopis lateromaculata* (underlined accession numbers refer to museum specimens catalogued as *H. marmorata* or as *Haemopis*). Most of these misidentified specimens had been catalogued and accessioned into the museum collections before the work of Mathers (1963) had been completed and published.

Alaska: USNM *19230* Yes Bay, *20732* Afognak Island, *21255* Yes Bay, *21256* Sanak Island, *43455* Revillagigedo Island, CMNA *1982-0746* Esther Island, and PH collections from Susitna River drainage, Kenai Peninsula, and Kodiak Island.

Western Canada: Yukon Territory: PH collection from Pelly River drainage (Yukon River drainage); British Columbia: USNM *19231* North Fork Moose River (at least two Moose Rivers occur in British Columbia), and USNM *38352* "D" [Dee] Lake; CMNA *1985-0289* and CMNA *1990-0056* (identified by J. Madill, but was not found in the collection) Fraser River drainage; and from PH collections from the Fraser River drainage (CMNA *2006-0036*) and Haida Gwaii (Queen Charlotte Islands) (CMNA *2006-0037*); Alberta: CMNA *1978-0426* Mackenzie River drainage; and from PH collection Peace River drainage (Mackenzie River drainage) (CMNA *2006-0034*).

Lower western United States: Idaho: from PH collection in the Snake River drainage (Columbia River

Identification of leech specimens: external characteristics

TEETH. All of the *Haemopis lateromaculata* contained teeth (denticles). This characteristic would separate these specimens from *H. plumbea* and *H. grandis.* Four populations (Utah, Nevada, Wyoming, Montana) of *H. marmorata* were without teeth. One population (Utah) was collected in 1941 (USNM *50195*) and again in 1986 suggesting that the loss of denticles may be due to environmental or genetic factors resulting from colonization after the dessication of Lake Bonneville after 13 000 years ago.

POSTERIOR SUCKER. Although the posterior sucker is large (about ¾ the width of the body) in *Haemopis lateromaculata* and small (less than ½ the width of the body) in *H. marmorata* (Klemm 1985), the state of body relaxation was highly variable. This variability made the relative size of the posterior sucker to body width rather arbitrary.

PIGMENTATION. The dorsal surface of *Haemopis lateromaculata* was patterned with darker blotches or mottled, or large to small speckles, of frequent to rare numbers. The lateral margins were cream or yellow (shared with *H. terrestris*) and interrupted with irregular dark intrusions dorsally (a very diagnostic character), visible from both the dorsal and ventral surface [specimens from 14 sites: the Great Basin (8), Colorado River drainage (2), Great Plains (1), Columbia River drainage (2), and the Yukon River drainage (1)]; or with the lateral margins the same shade as the ventrum, without cream or yellow coloring [specimens from 21 sites: the Great Basin (2), Pacific Coast drainages (2), Fraser River drainage (1), Mackenzie River drainage (1), coastal islands and their adjacent shores of British Columbia and Alaska (17)]. The external characteristic that identified all of the specimens was the plain ventral surface. Mathers (1963: page 170) noted "with a few indistinct black and yellow blotches" on the ventral surface. I observed one specimen with an occasional speckle on the ventral surface.

The pigmentation of *H. marmorata* in western North America ranged from heavily blotched or mottled to heavily speckled or lightly speckled on both the dorsum and ventrum (61 sites), with the ventrum having subdued pigmentation of the same pattern. If either *H. lateromaculata* or *H. marmorata* were of the light- and/or dark-colored immaculate phase (Klemm 1985: page 155), pigmentation could not be used to identify these two species. The light-colored immaculate phase was not found in the living state in western North America, but only in preserved specimens in museums. The lack of a dorsal stripe excluded *H. terrestris*, *H. kingi*, and *H. septagon* from further consideration in this study.

MAXIMUM LENGTH (MM). *Haemopis lateromaculata*: Great Basin (90), Colorado River drainage (67), Columbia River drainagae (31), Mackenzie River drainage (83), Fraser River drainage (30), Queen Charlotte Islands (81), Yukon River drainage (82), Alaska (112), and Great Plains (50). *Haemopis marmorata*: Great Basin (112), Colorado River drainage (95), Columbia River drainage (121), Pacific Coast drainages (98), Fraser River drainage (98), and Great Plains (94). Length is highly variable, dependent upon both the age of living specimens and their state of relaxation during fixation.

GONOPORE POSITIONS. *Haemopis lateromaculata*: Male gonopore XI *b6* anterior ½; female gonopore XII *b6* anterior ½, as determined on two specimens with developed clitellum from Nevada and Yukon Territory. All gonopore positions were separated by 5 annuli and occurred on the anterior ½ of the annulus. *Haemopis marmorata*: Male gonopore XI *b*6 anterior ½; female gonopore XII *b*6 anterior ½, as determined on three specimens with developed clitellum from Nevada and Colorado. Most gonopore positions were separated by 5 annuli and occurred on the anterior ½ of the annulus. Three exceptions: male XI *b*6 mid-annulus and female XII *b6* mid-annulus, and male XI *b*6 mid-annulus and female XII *b*5 posterior ½ both from Arizona; and male and female on mid-annulus from British Columbia. Sawyer (1972) noted additional variations of the gonopores from mid-annulus to the furrow. The male and female gonopore separations excluded *H. septagon* from further consideration during this study.

Identification of leech specimens by reproductive organs

Figure 2 illustrates the mean measurements of the reproductive organ position and Table 2 lists the mean ± standard deviation. The posterior position of the left and right ejaculatory bulbs, the posterior position of the penis sheath loop and the vagina organs, and the anterior position of the prostate organ (anterior end of male atrium) were selected for their defined shape, largely attributed to the muscular nature of the organs (Richardson 1969). The organ positions were determined by vertical positioning of the organ with the annulus, and hence counting the number of annuli to the annulus with the female gonopore. There is a possible error of annuli count of ±1 annulus due to the positioning in individual specimens. The nomenclature of the organs follows that of Klemm (1985). Left and right positions are determined from the dorsal side. Comparison to

other species is based on literature (Klemm 1985; Mann 1954; Richardson 1971).

PENIS SHEATH LOOP. *Haemopis lateromaculata*: The penis sheath loop was located at annulus XIII *b5* (XII *b6* to XIV *a2*). The penis sheath was generally U-shaped and distinguished *H. lateromaculata* from *H. marmorata*, *H. plumbea*, *H. terrestris*, *H. septagon*, and *H. caballeroi*. *Haemopis marmorata*: The penis sheath loop was located at annulus XVII *b1* (XV*b1* to XVIII *b5*), a range comparable to Sawyer (1972). The penis sheath was generally J-shaped and on the left side. The ranges did not overlap between *H. lateromaculata* and *H. marmorata*. The average length of the penis sheath of *H. lateromaculata* was 21 annuli and of *H. marmorata* 38 annuli between the male gonopore and the prostate gland. Abnormal variations for the penis sheath of *H. lateromaculata* include position on the right side (4 specimens from Yukon Territory, Alaska, and Colorado) and highly contorted (1 specimen from Alaska). Abnormal variations for the penis sheath of *H. marmorata* include: positioned on the right side (11 specimens from Great Basin, Colorado River Basin, and Great Plains), and highly contorted (6 specimens from Great Basin, Great Plains) with one specimen in which the terminal loop turns medially and is twisted to form a topless "8".

PROSTATE GLAND. *Haemopis lateromaculata*: The anterior end of the male atrium is covered by the prostate gland and was located at annulus XI *a2* (X *a2* to XII *b6*), positions that are anterior to the female gonopore and for the most part anterior to the male gonopore. These locations are associated with the U-shaped penis sheath. *Haemopis marmorata*: The anterior end of the prostate gland was located at annulus XIV *b5* (XIII *b1* to XVI *b5*), defining the J-shaped penis sheath.

EJACULATORY BULBS. *Haemopis lateromaculata*: The posterior end of the left ejaculatory bulb (seminal vesicle) was located at annulus XIII *b2* (XII *b2* to XIV *a2*) whereas the posterior end of the right ejaculatory bulb was at annulus XIII *b1* (XII *b1* to XIV *a2*). Although the locations show left-right symmetry (Figure 2), large variations were found in which the left bulb was 10 annuli posterior to 7 annuli anterior of the right bulb. The distribution of the positions of the ejaculatory bulbs was: right anterior to the left, 13 specimens; right even with the left, 13 specimens; and right posterior to the left, 8 specimens). *Haemopis marmorata*: The posterior end of the left ejaculatory bulb was located at XIV *b2* (XIII *b1* to XV *b5*) whereas the posterior end of the right ejaculatory bulb was at annulus XIV *b1* (XII *a2* to XV *b6*). The left bulb ranged from 9 annuli posterior to 5 annuli anterior of the right bulb. The distribution of the ejaculatory bulbs was: right anterior to the left, 19 specimens; right even with the left, 16 specimens; and right posterior to the left, 17 specimens), a pattern noted by Sawyer (1972). Two specimens had only one ejaculatory bulb.

VAGINA. *Haemopis lateromaculata*: The posterior end of the vagina (vaginal bulb) was found at XIV *b6* (XIII *a2* to XVII *a2*). The vagina was always posterior to the posterior reach of the penis sheath loop and was generally in the median region. *Haemopis marmorata*: the posterior end of the vagina was found at XVI *b1* (XIV *b2* to XVII *a2*), comparable to the findings of Sawyer (1972). The vagina was always anterior to the posterior reach of the penis sheath loop and posterior to the anterior end of the prostate gland, and generally located in the medial region. Three specimens had the vagina location anterior to the anterior end of the prostate gland. The position of the vagina of *H. caballeroi* had a relative position to the penis sheath loop and the prostate gland (atrium) as in *H. marmorata*, but the two specimens of *H. caballeroi* were highly contracted and hence not typical (Richardson 1971). The extensive penis sheath and its relation to the vagina suggests that these two species deserve a separate genus — in

TABLE 2. Annuli location of selected reproductive organs in *Haemopis marmorata* and *H. lateromaculata*. Annulus X *b1* was number 1 and annuli posterior to this annulus were sequentially numbered. Organ nomenclature was taken from Klemm (1985). Figure 2 illustrates the organs and the points of measurement.

	H. lateromaculata N = 31	*H. marmorata* N = 55
Penis sheath loop		
Mean ± standard deviation	18.8 ± 2.6	35.8 ± 4.6
Range	14 – 23	25 – 44
Anterior prostate gland

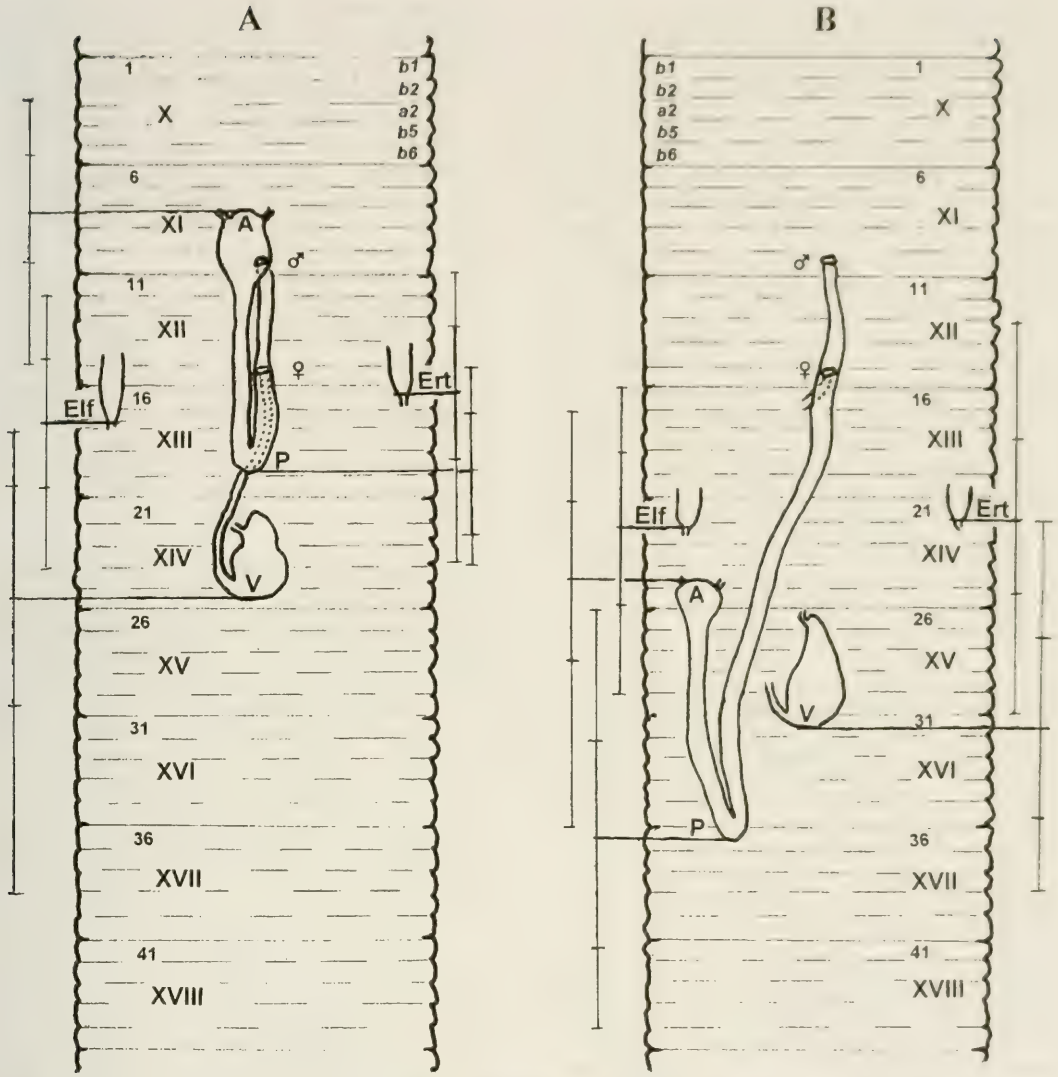

FIGURE 2. Measured reproductive organs in *Haemopis lateromaculata* (A) and *H. marmorata* (B), viewed from the dorsum. The segments are shown in Roman numerals starting with segment X and extend to segment XVIII. Each segment has five annuli as denotated names shown on the right side of segment X. For the purposes of this paper, the first annulus is numbered 1 and is sequenced posteriorly as noted on the left side with only the first annulus of each segment numbered (see Table 2). Male gonopore on IX *b6* and female gonopore on XII *b6*. Denotations: Elf, posterior reach of the left ejaculatory bulb; Ert, posterior reach of the right ejaculatory bulb; P, posterior reach of the penis sheath loop; V, posterior reach of the vagina; and A, the prostate gland at the anterior end of the male atrium. The vertical lines represent one standard deviation (thick lines) and total range (thin lines) (see Table 2).

this case *Percymoorensis*, if one follows the distinct genera classification in Erpobdellidae of *Nephelopsis*, *Mooreobdella*, and *Erpobdella*, each having morphological distinct male atriums and sperm ducts.

Discussion

Haemopis lateromaculata is now considered to be widely distributed throughout North America; prior to this study, its known distribution had been limited to two states (Figure 1). The presence of this leech on the Alaskan Peninsula and adjacent islands, the Cook Inlet region, the Alexander Archipelago of southeast Alaska, and Haida Gwaii (Queen Charlotte Islands) of British Columbia suggest that these leeches occupied off-shore coastal refugia during the Pleistocene and were separated from those populations south of Canada's cordil-

leran and continental glaciers. These northwest refugia were limited by extensive glaciers from Haida Gwaii to Umnak Islands (Coulter et al. 1965; Clague 1989; Kaufman and Manley 2004) with coastal cordilleran glaciers occurring to 12 000 years ago (Peltier 1994; Dyke 2004; Fulton et al. 2004). While the occurrence of small terrestrial refugia have been postulated from Kodiak to the Queen Charlotte Islands (Heusser 1989; Ramsey et al. 2004), present day freshwater habitats (ponds, lakes, slow moving and meandering streams) from which leeches have been collected add a new dimension to the terrestrial refugia.

The Pleistocene-Holocene environments were changing due to eustasy (the sea level rising at least 120 m) and glacio-isostatic surface adjustments involving the advance and recession of the glaciers. Hetherington et al. (2003, 2004) mapped this environment for the Haida Gwaii and described a land bridge between the islands and the British Columbia mainland that existed between 11 700 and 11 200 years ago as a result of the presence of a forebulge from the retreating cordilleran glacier. This process, if applied throughout the glaciated region of coastal Alaska, may have allowed island by island transfer of leeches from coastal Pleistocene refugia, thus accounting for the modern day presence of *H. lateromaculata* populations on the coastal northwestern North America mainland (Reimchen and Byun 2005). Upstream movement of *H. marmorata* has been noted (Herrmann 1970; Richardson 1942; Sawyer 1970), and active movement (to Prince Edward Island) must have occurred by direct means, and not as passive movement by birds or other agents (Richardson 1943). It is assumed herein the cordilleran glaciers and marine habitats prevented any leeches from continental populations colonizing the coastal habitats.

Lukin (1976) suggested that *Haemopis* originated in the Nearctic and penetrated the Palaearctic from the northeast [Siberia] when northern Asia had a warmer climate. He further suggested that *H. sanguisuga* emerged at that time and is now found across central Eurasia to the Amur Basin and near Vladivostok in eastern Asia, but not in Kamchatka Peninsula. The center of biodiversity of *Haemopis* is in eastern North America, supporting Lukin's postulate. Only two species (*H. lateromaculata* and *H. marmorata*) moved out of this region to occupy most of North America, and only *H. lateromaculata* has been identified in Alaska and the coastal islands, suggesting range expansion in an earlier epoch before the range expansion of *H. marmorata.* From the Late Cretaceous (80 million years ago) to the middle Pliocene (3 million years ago), North America and eastern Asia were connected between Alaska and eastern Siberia (Repenning and Brouwers 1992; Smith et al. 1994). For much of this time, the climate in this region was comparable to that of the southeastern United States today (Bassinger 1991).

I propose that *H. lateromaculata* and *H. sanguisuga* are sister species. Two anatomical features of *H. lateromaculata* and *H. sanguisuga* support this relationship: (1) the vaginal bulb lies posterior to the penis sheath loop (shared with *H. grandis* and *H. kingi*) and (2) the prostate gland (anterior end of the male atrium) occurs mostly anterior to the male gonopore (shared with *H. kingi* and *H. caeca*) (Mann 1954; Klemm 1985; Manoleli et al. 1998). Note that *H. kingi* occurs in both groups, a confirmation of Richardson's (1969, 1971) views that *H. kingi* and *H. lateromaculata* are closely related.

The distribution of a species is as important as the original description of a species. As noted by Newton (2003: page 90) with respect to birds, "how species are formed is central to understanding their distributions" and "genealogy and distribution are not separate issues: they are simply different sides of the same biological coin". This paper contributes to the definition of *H. lateromaculata* by the addition of geographical limits of its distribution and its evolutionary implications.

Acknowledgments

I thank Jacqueline Madill and Jean-Marc Gagnon at the Canadian Museum of Nature, Bill Moser at United States National Museum (Smithsonian Institution), and John Keebaugh at the Orma J. Smith Museum of Natural History for assistance and for providing facilities at these museums which greatly contributed to this study; Robert Wisseman (Aquatic Biology Associates) and Kurt King (Wyoming Department of Environmental Quality) for furnishing leeches for identification from western United States. Early versions of this document were reviewed by Bill Moser and Donald Klemm, and Jacqueline Madill and Mark J. Wetzel reviewed the manuscript for the journal. I thank these reviewers for their suggesting and improvements.

Jennings, J. B., M. L. Kennedy, A. E. Houston, and B. D. Carver. 2006. Predation on artificial nests of Northern Bobwhites, *Colinus virginianus*, by mammalian mesopredators: Does the problem-individual paradigm fit? Canadian Field-Naturalist 120(4): 452–456.

Using mark/recapture procedures, predation on artificial nests of Northern Bobwhites (*Colinus virginianus*) by mammalian mesopredators (Raccoons, *Procyon lotor*; Virginia Opossums, *Didelphis virginiana*; and Striped Skunks, *Mephitis mephitis*) was assessed in relation to the "problem-individual" paradigm. The paradigm, which is untested among mammalian mesopredators, predicts that most predation on a prey species is by a small number of individuals repeatedly involved. By examining number of captures and recaptures on artificial nests during non-nesting and nesting periods in 2000-2003, predation within and among species were gauged. Results varied by species, sampling period, and year; however, predation was by a small percentage of individuals and only within the population of Striped Skunks were individuals (2 of 49) captured on an artificial nest more than once. Raccoons, Virginia Opossums, and Striped Skunks were responsible for 10, 2, and 12% of the loss of all nests available to predators, respectively. Based on low occurrences of individuals repeatedly involved in predation on nests, the problem-individual paradigm was unsubstantiated. Although Raccoons, Virginia Opossums, and Striped Skunks (as individual predators) had only moderate impact on the population of Northern Bobwhites, they had a much greater impact collectively (preying upon 24% of all nests available). To maximize Northern Bobwhite success, the most productive management is probably best directed toward a vertebrate guild that includes mammalian, avian, and reptilian predators, and management strategies that use multiple techniques.

Key Words: Raccoons, *Procyon lotor*, Striped Skunks, *Mephitis mephitis*, Virginia Opossums, *Didelphis virginiana*, Northern Bobwhites, *Colinus virginianus*, artificial nests, problem individuals, predation, Tennessee.

Due to several factors (e.g., release of predators and reduced hunting; Young and Ruff 1982; Amarasekare 1993; Mosillo et al. 1999), populations of Raccoons (*Procyon lotor*), Virginia Opossums (*Didelphis virginiana*), and Striped Skunks (*Mephitis mephitis*) have increased in abundance throughout much of their range. These increases have caused widespread removal to be attempted as one means of controlling populations of these species (United States Department of Agriculture 2004*). Linnell et al. (1999), in discussing carnivore-livestock conflicts, pointed out that individuals or demographic groups within a predator population can show different behavioral traits where only a small proportion of individuals is accountable for taking significant numbers of a prey species. They refer to the phenomena as the "problem-individual" paradigm. Although this paradigm appears to fit some larger carnivores (Rabinowitz 1986; Ross et al. 1997; Sacks et al. 1999; Stahl et al. 2001), the hypothesis rarely has been tested (Linnell et al. 1999). Presently, the existence of individuals or a demographic group within mid-sized mammalian predators that prey upon a disproportionate number of nests of ground-nesting birds is unknown. Different rates of predation, by individuals or species, could allow for targeted removal of individuals rather than widespread removal as a means of controlling nest predation which may have broad conservation and management application as fewer individual predators would need to be removed.

Mammalian mesopredators are among the known predators of Northern Bobwhites (*Colinus virginianus*; Leimgruber et al. 1994; Fenske-Crawford and Nieme 1997), and populations of this game bird have declined throughout most of its range (Brennan 1991). However, causes of mortality for Northern Bobwhites are not well understood (Burger et al. 1995), and rates of predation within and among species of mammalian predators on Northern Bobwhites are uncertain. Additionally, mid-sized mammalian predators have been successfully captured and recaptured in live traps (Johnson 1970; Baldwin et al. 2004) and have been shown to prey upon artificial nests of Northern Bobwhites (Leimgruber et al. 1994; Fenske-Crawford and Niemi 1997); therefore, they make a good model for assessing the "problem-individual" paradigm using capture/recapture procedures.

The purpose of the present study was to examine the "problem-individual" paradigm in light of predation by populations of mammalian mesopredators on artificial nests of Northern Bobwhites. Specifically, the prediction was tested that predation on artificial nests of Northern Bobwhites by Raccoons, Virginia Opossums,

and Striped Skunks is not widespread within and among species. This work should assist in developing sound conservation and management programs for Northern Bobwhites and control of mammalian mesopredators.

Methods

This investigation was conducted on the Ames Plantation (Ames; 35°4'N, 89°13'W), an agricultural experiment station of The University of Tennessee and home to the National Field Trial Championship for bird dogs, located in Hardeman and Fayette counties, Tennessee. Ames was approximately 7500 ha and consisted of a mosaic of habitat types that included agricultural fields, pastures, upland hardwoods, bottomland hardwoods, and pine plantations. On the site, about 2000 ha were managed extensively for Northern Bobwhites. The site provided sufficient bird populations (autumn densities of ca. 2-3 birds/ha; Seckinger 2004) and associated predator suite (Leberg and Kennedy 1988; Baldwin 2003; Baldwin et al. 2004) to allow study of a ground nesting bird. For a more detailed description of Ames see Baldwin et al. (2004).

Two study sites (separated by 1.6 km) were sampled. Each was 1.6 km^2 and was similar in habitat (fragmented, upland hardwood forest interspersed with early successional fields). Because results obtained at each site were similar, results are combined and are presented here. Trapping during the non-nesting season (October-December 2000-2002) was conducted using Raccoon-size live traps (81.3 × 25.4 × 30.5 cm; Tomahawk Live Trap Co., Tomahawk, Wisconsin, or Havahart Live Traps, Woodstream Corporation, Lititz, Pennsylvania), which were baited with cat food and placed in an 8 × 8 configuration with traps spaced at about 230-m intervals. Sampling was conducted for 32 nights/season (for a total of 2000 trap nights/season). Once captured, sex and age were determined, and individuals were tagged (National Band and Tag Company, Newport, Kentucky) in both ears. Additionally, to confirm that individuals remained on the study site during the nesting season, 17, 3, and 3 Raccoons; 10, 9, and 5 Virginia Opossums; and 7, 8, and 1 Striped Skunks were fitted with radiocollars in 2000, 2001, and 2002, respectively. Animals were verified as being on the study site using a three-element hand-held antenna and a portable receiver. Telemetry equipment was from Advanced Telemetry Systems, Inc., Isanti, Minnesota. All individuals were released at the site of capture. Work during this period provided a known number of marked individuals that could be compared to those individuals captured during the nesting trapping season.

Results obtained during the nesting trapping season (June-September 2001-2003) were derived using artificial nests (10 cm wide by 6 cm deep) and baited with two eggs of Northern Bobwhites (Hernandez et al. 2001). The nest itself, constructed from wicker, was commercially purchased. Before placement, nests were left outdoors in an undisturbed state for 5-7 days to minimize human odors as suggested by Donalty and Henke (2001). Predators can cue on human odors at artificial nests (Whelan et al. 1994), but this can be minimized by rain or scents (Donalty and Henke 2001). To address this concern, eggs were rinsed with distilled water and handled with rubber gloves when placed on nests (Small and Hunter 1988). By comparing individuals of the known population (non-nesting season captures) that also were captured on artificial nests during the nesting season, the percentage of the population actively involved in predation on artificial nests was determined.

Artificial nests were placed inside live traps. At each site, 80 traps were established; 50 were in actual use at any one time. Traps were placed either selectively or randomly which resulted in an irregular distribution over each of the 1.6 km^2 study areas. Because of this placement of traps, artificial nests occurred in a variety of habitat types which can be typical of Northern Bobwhites (Stribling 1996). Traps that were without nests were wired open. All traps were camouflaged with available vegetation. Once a nest was preyed upon, another trap (randomly or selectively placed) in another location had an artificial nest placed inside. Traps with a preyed-upon nest were closed and no longer used. This provided 50 nests on each of the two sites to be in continuous use. Traps in operation were open for 90 nights/season (for a total of 9000 trap nights/season), and were checked daily. To minimize animals associating traps with nests, 25 pseudo-nests were established on each site. These were made of chicken wire in the shape and size of the actual traps used to contain artificial nests. Pseudo-nests were not baited and were randomly placed in the study areas.

Results

For comparisons between nesting and non-nesting seasons, radiotelemetry procedures confirmed that 9 Raccoons, 1 Virginia Opossum, and 2 Striped Skunks, which were radiocollared during the non-nesting season (2000), were present during the nesting-trapping season (2001). Three Raccoons collared in the non-nesting sessions (2000) along with 1 Striped Skunk were present on the study area for the nesting-trapping session (2002). There also was one Raccoon and one Striped Skunk collared during the non-nesting-trapping session (2002) present on the study area for the nesting-trapping session (2003).

Capture data derived from the two sampling periods varied somewhat by species, year, and sampling period (Table 1). Sampling during the non-nesting period revealed the presence of all target species, with the greatest number of individuals varying by species each year. Sampling during the nesting period also showed presence of all targeted species during each year but in smaller numbers and with less variation in data across years than observed in the non-nesting period.

TABLE 1. Capture data derived in a study of predation by mammalian mesopredators (Raccoons, Virginia Opossums, Striped Skunks) on artificial nests of Northern Bobwhites during two trapping sessions (non-nesting, nesting) on the Ames Plantation in western Tennessee 2001-2003. C = number of individuals captured; R = number of individuals recaptured at least one time during the same trapping session of the same year; %R = percentage of marked individuals recaptured (R/C × 100); M = number of individuals captured > 2 times; %COL = the percentage of radio-collared animals captured (number of collared animals recaptured/total number collared × 100%); T = number of individuals captured during the non-nesting period that were recaptured during the nesting period; %K = percentage of individuals captured during the non-nesting period that were recaptured during the nesting period (T/C of the Non-nesting period × 100%).

		Non-nesting (October–December)					Nesting (June–September)					Captured during both seasons	
Year	Species	C	R	%R	M	%COL	C	R	%R	M	%COL	T	%K
2001	Raccoon	41	24	59	6	18	13	0	0	0	11	4	10
	Virginia Opossum	33	13	39	8	10	3	0	0	0	0	0	0
	Striped Skunk	12	5	42	4	43	22	1[1]	5	1[1]	0	1	8
2002	Raccoon	19	8	42	1	0	14	0	0	0	33	0	0
	Virginia Opossum	19	9	47	6	0	3	0	0	0	0	0	0
	Striped Skunk	24	12	50	7	0	11	1	9	0	0	1	4
2003	Raccoon	38	17	45	4	0	16	0	0	0	0	3	8
	Virginia Opossum	89	24	27	9	20	4	0	0	0	0	1	1
	Striped Skunk	46	18	39	8	0	16	0	0	0	0	0	0

[1] This reflects predation by the same individual.

The total number of nests available to predators was 433. Raccoons were responsible for 43 nests preyed upon (10% of all nests available to predators). Virginia Opossums were responsible for predation on 10 nests (2%), and Striped Skunks destroyed 52 nests (12% of all nests available). Collectively, these predators preyed upon 24% of all available nests. No significant pattern existed in the age or sex of the predators involved in predation on artificial nests.

Discussion

Results of this study documented that at most only 10% of a known predator population (Table 1) was actively involved in predation on artificial nests of Northern Bobwhites. Additionally, individual predator species were involved in predation on artificial nests to varying levels (Table 1). Based on these results, the prediction that predation on artificial nests of Northern Bobwhites by Raccoons, Virginia Opossums, and Striped Skunks is not widespread within and among species, is supported, and the "problem-individual" paradigm is unsubstantiated. All predators assessed had members captured multiple times during the non-nesting season. These results were similar to those reported in other studies of mesopredators conducted during autumn and winter (non-nesting seasons) in the region (Ladine 1995; Baldwin 2003). Such results demonstrate that individuals can be captured and recaptured in suitable numbers to explore the "problem-individual" paradigm. However, only two Striped Skunks were captured on artificial nests more than once. Given that these individuals represented only 2 of 49 Striped Skunks captured and were only captured 2 and 3 times, respectively, in the present study and that Vickery et al. (1992) reported predation by Striped Skunks on nests of birds was not targeted, these results do not corroborate the "problem-individual" paradigm. Additionally, in comparison with larger mammalian predators, this paradigm has been associated, generally, with much higher levels of predation and by greater numbers of individuals repeatedly involved in taking prey (Claar et al. 1986; Stander 1990; Ross et al. 1997; Sacks et al. 1999; Stahl et al. 2001). Scalet et al. (1996) pointed out that predator-prey interactions influence both prey and predator populations. However, based on results of the present study, these interactions appear to be complex and differ among mammalian taxa.

Lack of support for the "problem-individual" paradigm among target predators could be explained by distribution of nests of Northern Bobwhites on the landscape and the predators involved. Stribling (1996) noted that nests of Northern Bobwhites are located in a number of habitat types. Linnell et al. (1999) suggested that a scattered distribution of prey, such as the distribution of artificial nests in this study, would increase encounter rates by predators without any search behavior required, and hypothesized that, under these conditions, problem individuals are less likely to appear because most individuals have opportunity to take the target prey without developing specialized behaviors.

Raccoons, Virginia Opossums, and Striped Skunks are omnivorous and opportunistic predators with strong preferences for seasonally available foods (McManus 1974; Gardner 1982; Godin 1982; Kaufmann 1982; Schwartz and Schwartz 2001). Wiens (1976) discussed population responses to patchy environments and noted the importance of prey density to responses of populations to patchiness. It appears likely that the habitat usually occupied by Northern Bobwhites (forest openings, open woods, fallow fields, and edges of cultivated fields; Stribling 1996) provides favorable and abundant foods (e.g., insects and other invertebrates, wild fruits, and small mammals; Merritt 1987; Schwartz and Schwartz 2001) for mammalian predators. Given that

number of individuals known alive for each species of predator was greater on the study site during the non-nesting period than the nesting period, as well as overall recapture rate and number of individuals captured more than 2 times (Table 1), it seems that the presence of eggs of Northern Bobwhites and Northern Bobwhites themselves had no unusual attraction for mesopredators. Neither Raccoons nor Virginia Opossums had a significant affinity for fields, which are managed intensively for Northern Bobwhites on Ames, and, because of the lack of individuals recaptured on artificial nests, the problem-individual hypothesis is not supported for these species. However, based on the number of captures in the present study, there was a distinct association between fields and Striped Skunks, which reflects a preference for this habitat (Nowak 1991). These habitats also are good for Northern Bobwhites throughout the year and not just during their breeding season (Stribling 1996). These mesopredators apparently used the study site and adjacent areas during the nesting period of Northern Bobwhites for foods other than those associated with Northern Bobwhites.

Being opportunistic, mesopredators may prey upon nests of Northern Bobwhites when they encounter them. Because of increased protein intake during formation and laying of eggs (Rosene 1969), eggs and Northern Bobwhites themselves represent foods of high nutritional value. However, because Northern Bobwhites on Ames provide only a limited source of food, optimal foraging is likely focused on more abundant and easily captured food items. Eggs and birds probably serve as a valuable supplemental food to more abundant food items. For example, Vickery et al. (1992) reported a positive correlation between predation by Striped Skunks on bird eggs and nestlings when that species was foraging for invertebrates. Such foraging patterns could partly explain reports that birds are preyed upon by Raccoons, Virginia Opossums, and Striped Skunks, although their occurrence in diets of these predators is small (McManus 1974; Kaufmann 1982; Godin 1982; Schwartz and Schwartz 2001).

In the present investigation, there was only one year where the most abundant species captured during the non-nesting season was responsible for the greater numbers of artificial nests preyed upon during the nesting-trapping season (Table 1). It appears that Raccoons, Virginia Opossums, and Striped Skunks, as individual species, had only a moderate impact on artificial nests (Table 1). However, as a subset of the community or mesopredator guild—a collection of species that use common resources in similar ways (Root 1967)—they had a much greater impact. In fact, Nicolaus (1987) stated that Raccoons, along with other mammals and birds, belonged to a guild of nest predators. Of artificial nests preyed upon in this study, Raccoons, Virginia Opossums, and Striped Skunks accounted for 10, 2, and 12% of losses, respectively. Collectively, there was a 24% loss of artificial nests attributable to this mesopredator guild.

Overall, the pattern of predation on artificial nests of Northern Bobwhites is apparently driven by a larger vertebrate-predator guild similar to the granivore guild (birds, rodents, and insects) reported in deserts of the southwestern United States (Brown and Davidson 1977). This vertebrate-predator guild, including both mammalian and reptilian predators, also has been documented by Staller et al. (2005). Because of the collective predation rates on artificial nests, most productive management (using multiple techniques; Jiminez and Conover 2001) for ground-nesting birds probably is best directed toward a vertebrate guild that includes not only mammalian predators but avian and reptilian predators as well. Because of the dynamic nature of community interactions (Meffe et al. 1997), it is not likely that single actions will resolve complex predator-prey relationships, which reflect the dynamic nature of the ecological world. At present, interaction among mammalian mesopredators is uncertain (Ladine 1997; Kissell and Kennedy 1992) and the impact of large vertebrate-predator guilds on prey species remains unclear. Future investigations are needed to more clearly understand these ecological issues.

Acknowledgments

Thanks are extended to T. L. Best, S. B. Franklin, J. W. Grubaugh, and B. A. Simco who provided a critical review of an earlier draft of the manuscript. R. A. Baldwin, B. D. Carver, J. R. Hisey, and R. C. Whittington contributed to numerous aspects of the study. Gratitude also is extended to the Ames Plantation for allowing access to lands under their control. This investigation was a cooperative project that included contributions from the Hobart Ames Foundation, Tennessee Wildlife Resources Agency, and The University of Memphis.

Laidre, Kristin, L., Mads Peter Heide-Jørgensen, and Jack Orr. 2006. Reactions of Narwhals, *Monodon monoceros*, to Killer Whale, *Orcinus orca*, attacks in the eastern Canadian Arctic. Canadian Field Naturalist 120(4): 457–465.

A Killer Whale attack on Narwhals was observed at Kakiak Point in Admiralty Inlet, Nunavut, Canada, in August 2005. Behavioral responses of both Narwhals and Killer Whales were documented by direct observation. Data collected from Narwhals instrumented with satellite-linked transmitters 5 days prior to the arrival of Killer Whales were used to examine changes in Narwhal movement patterns (e.g., dispersal and clumping) five days before the attack, during the attack, and five days after Killer Whales left the area. A minimum of four Narwhals were killed by 12-15 Killer Whales in a period of 6 hours. Narwhals showed a suite of behavioral changes in the immediate presence of Killer Whales including slow, quiet movements, travel close to the beach (<2 m from shore), use of very shallow water, and formation of tight groups at the surface. These behavioral changes are consistent with Inuit accounts of Killer Whale attacks on Narwhals. During the attack, Narwhals dispersed broadly, the groups were less clumped (standard deviation of inter-whale mean latitudes and longitudes), Narwhal space-use doubled from pre-attack home ranges of 347 km^2 to 767 km^2 (kernel 50% probability), and Narwhals shifted their distribution further south of the attack site. After the disappearance of Killer Whales, north-south dispersal of Narwhals contracted and was similar to pre-attack levels, total space use decreased slightly (599 km^2), yet west-east dispersal remained high. Narwhals were distributed significantly ($P < 0.001$) more broadly offshore in areas not used before the occurrence of Killer Whales. In general, short-term reactions of Narwhals to Killer Whale presence were obvious; yet normal behavior (as observed from shore) resumed shortly after Killer Whales left the area. Long-term (five day) Narwhal behavioral responses included increased dispersal of Narwhal groups over large offshore areas. This is among the few reports of eyewitness Killer Whale attacks on Narwhals in the high Arctic and is the first time changes in Narwhal behavior have been documented in response to a predation event through the use of satellite telemetry.

Key Words: Killer Whale, *Orcinus orca*, Narwhal, *Monodon monoceros*, predation, satellite telemetry, Admiralty Inlet, Nunavut, Canada.

Killer Whales (*Orcinus orca*) occur widely in Arctic waters, yet their abundance, movements, site fidelity, and specific distribution are poorly known (Forney and Wade 2006). Generally, Killer Whales are sighted during ice-free months and often near areas with high densities of other marine mammals, such as summering grounds for Belugas (*Delphinapterus leucas*) and Narwhals (*Monodon monoceros*). In the eastern Canadian High Arctic, this includes eastern Lancaster Sound and associated inlets or fjords around Baffin Island (e.g., Eclipse Sound, Admiralty Inlet, and Prince Regent Inlet) (Markham 1874; Reeves and Mitchell 1988).

Few eyewitness accounts are available of Killer Whale attacks on Narwhals (Steltner at al. 1984). This is because Killer Whales occur over large, sparsely inhabited Arctic areas and the timing and location of attacks are unpredictable. Thus, the majority of descriptions, both of Killer Whale attacks themselves and of the response of Narwhals, come from Inuit observations (Degerbøl and Freuchen 1935; Freuchen and Salomonsen 1961) or from scattered opportunistic reports (Campbell et al. 1988). Generally these accounts made by locals are limited in that observations extend only as far as what can be observed from shore and generally cover short time scales (hours). Also, Inuit observations of Killer Whale occurrence or Killer Whale attacks may not always be reported. There is little information about the natural mortality of Narwhals and generally, Killer Whales are assumed not to significantly depress Narwhal populations (Davis et al. 1980). Furthermore, the extent to which Killer Whales affect the behavior of Narwhals (e.g., movement patterns) is unknown.

In August 2005, a Killer Whale attack on Narwhals was observed from a camp operating a month-long Narwhal satellite tagging operation in Admiralty Inlet, Canada. Several kills of Narwhals by Killer Whales were inferred from vigorous surface and diving activity of Killer Whales within large oiled areas on the surface and congregations of seabirds. In combination with eyewitness observations of behavior of Narwhals and Killer Whales, data collected from satellite tags deployed on Narwhals up to five days before Killer Whales arrived in the area were used to examine clustering and dispersal of Narwhals prior to and following the predation events. These are the first quantitative movement data obtained from Narwhals subjected to Killer Whale predation.

Visual Observations of Attack

Killer Whales were reported by Inuit hunters in a camp about 3 km north of Kakiak Point (72°31'N 86°38'W), in Admiralty Inlet, Nunavut, Canada, on 19 August 2005. On 20 August, we witnessed a Killer Whale predation event on Narwhals just offshore of Kakiak Point. Approximately 12-15 Killer Whales arrived in a single group at Kakiak Point at 12 noon local time. At least several hundred Narwhals had been seen daily in the area for at least two weeks preceding the arrival of the Killer Whales and also on the morning of 20 August. On several occasions thousands of Narwhals had been seen moving past Kakiak Point over periods of 2-3 hours.

The Killer Whale group consisted of one adult male, 7-10 adult females, and several juveniles of undetermined sex. Narwhals were attacked less than 1 km from shore. At least two Narwhals were killed during the first observed attack between 12:00-13:00 local time. After this event, the Killer Whales left the vicinity of Kakiak Point for approximately 3 hours and returned at 16:00, when at least two more Narwhals were killed ~0.5 km from the coast. Killer Whales were not seen or reported again in the area until 25 August. Active subsistence hunting for Narwhals was practiced at several hunting camps along the shore north and south of the research camp.

The four independent kill events occurred over a 6 hour period in daylight hours. Narwhal kills were inferred from large oil/blubber slicks at the surface, congregations and diving of Fulmars (*Fulmarus glacialis*) in surface waters, and focal movements of Killer Whales diving in the center of oiled areas for 15-30 minutes at a time (Figure 1). No body parts or pieces of Narwhals were directly seen.

Narwhal Movements

Narwhal satellite tagging operations were ongoing prior to the Killer Whales' arrival at Kakiak Point. Narwhals were captured using nets set perpendicular to the shoreline 50-100 m from shore (details described in Dietz et al. 2001) and instrumented with SPOT4 and SPOT5 satellite tags made by Wildlife Computers (Redmond, Washington). Tags recorded daily geographic positions based on Doppler shift of tag transmissions received by polar orbiting satellites through Service Argos (Harris et al. 1990). Transmitters were attached to Narwhals on the dorsal ridge with three 6-10 mm polyethylene pins. The Narwhals were usually released after less than 30 minutes (Table 1).

Only data collected from Narwhals instrumented prior to the Killer Whales' arrival were used in the analysis to control for differences in sample size (number of individuals monitored before and after the predation event). Since the Narwhals were instrumented and released on different occasions, they were assumed to represent different groups or pods. Average daily geographic positions were calculated for each Narwhal based on good quality Argos locations (location quality >=0). Average daily positions for each whale were averaged to create inter-whale means. The standard deviation of daily average inter-whale positions was calculated for each of three time periods: five days before Killer Whales arrived (14–18 August), during the immediate Killer Whale observations or attacks (19–20 August), and five days after the Killer Whale attack (21–25 August) when no Killer Whales were seen in the area. Narwhals were distributed along a north-south gradient along the west coast of Admiralty Inlet; therefore the variation in latitude was interpreted as coastwise dispersion and the variation in longitude was interpreted as inshore-offshore dispersion. Narwhal space-use patterns were quantified in each of the three time periods with a kernel home range polygon (probabilistic measure of space use) [ArcView 3.1 Environmental Systems Research Institute] based on average daily positions from each whale.

Results

Pre-attack Narwhal behavior (> 5 days)

Narwhals observed passing Kakiak Point before the Killer Whale attack moved in groups of 3-8 whales at a distance of 20-200 m from the beach. Most whales were heading south. Between 14 and 17 August, seven Narwhals were instrumented with satellite tags before the Killer Whales arrived in the vicinity of Kakiak Point (Table 1). These Narwhals moved along the western side of Admiralty Inlet south of Kakiak Point and less than 1-2 km from shore. No tagged Narwhals were located in the center or eastern side of the inlet and the linear home range along the west coast was <100 km.

TABLE 1. Seven Narwhals instrumented with satellite transmitters prior to Killer Whale occurrence and attack at Kakiak Point, Admiralty Inlet, Canada, 2005. Calf accompanying female on 17 September 2005 was not tagged.

ID	Tagging date	Time of release	Sex	Body length (cm)
20685	14 September 2005	15:06	F	360
20686	14 September 2005	15:56	M	483
20689	17 September 2005	06:25	F	360
37235	17 September 2005	10:45	F + calf	358
37236	17 September 2005	21:20	F	380
37280	17 September 2005	21:27	F	380
37282	17 September 2005	21:45	F	364

FIGURE 1. Oil film on the surface created by Killer Whales feeding on Narwhals in Admiralty Inlet, Canada, August 2005. Large aggregations of Fulmars appeared in the area shortly after each kill. Photo by M. P. Heide-Jorgensen.

The standard deviation of average daily positions indicated that dispersal of Narwhal groups varied approximately 19.9 km north-south, and 13 km west-east before Killer Whales arrived (Table 2). The core of the pre-attack kernel home range (50% probability area) was concentrated just offshore of Kakiak Point and distributed along the west coast of the inlet encompassing 347 km^2 (Table 2).

Immediate Reactions of Narwhals to Killer Whale Attack

On 19 August, Killer Whales were reported by Inuit hunters north of the camp, yet no detailed observations of predation events or behavior were collected. On that day, we observed Narwhals passing very close to the shore (within the surf zone approximately 2-3 m from land) and remaining still at the surface in large groups.

TABLE 2. Dispersal of Narwhals before, during, and after a Killer Whale attack in August 2005 as measured by the distance between average daily satellite positions obtained from seven Narwhals instrumented at Kakiak Point prior to the arrival of the Killer Whales. The standard deviation (SD) in latitude and longitude is reported and also converted to north-south dispersal and west-east dispersal with distance units of km.

	Latitude SD	Longitude SD	N-S dispersal (km)	W-E dispersal (km)	Kernel core (50%) km^2
Before attack (5 days)	0.18	0.12	19.9	13.0	347
During attack (2 days)	0.33	0.29	36.4	32.8	767
After attack (5 days)	0.18	0.25	19.7	27.6	599

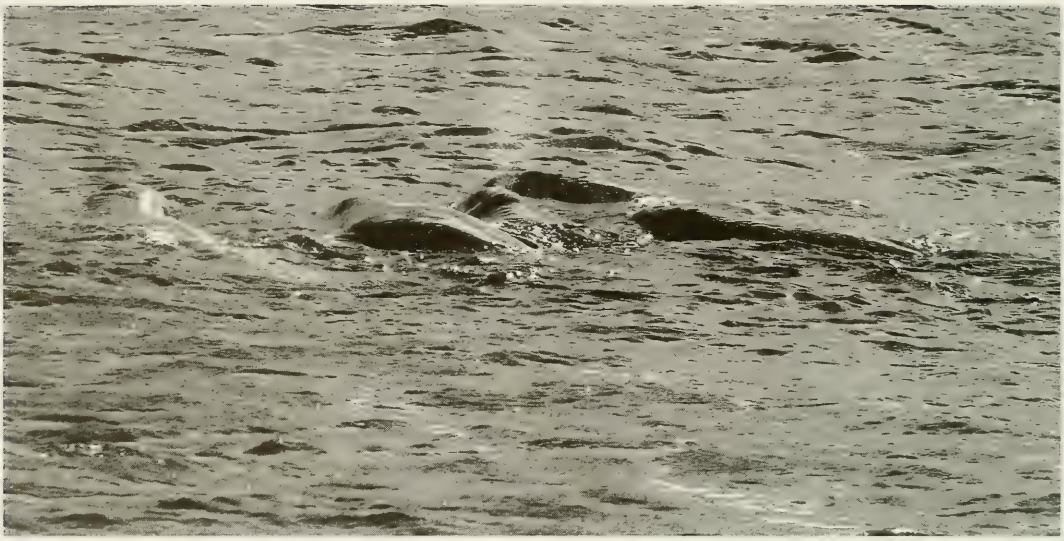

FIGURE 2. When Killer Whales arrived in the vicinity of Kakiak Point, Narwhals formed tight groups and remained close to the shore lying still. Photo M. P. Heide-Jørgensen.

On 20 August, Killer Whales were visually observed arriving at Kakiak Point traveling a northbound route along the west side of the inlet. Narwhals were already present in the coastal area (<500 m from the shore) around Kakiak Point and in a small bay just behind the point. When the Killer Whales were within 2-4 km, Narwhals suddenly moved closer to the shore in shallow water (<2 m). Some Narwhals formed tight groups and others moved slowly or lay very still at the surface (Figure 2). One Narwhal stranded on a flat gravel beach (<0.5 m of water) and made violent tail thrashes for >30 seconds (Figure 3), either as a warning signal or in attempts to remove itself from the beach.

Satellite telemetry data indicated instrumented Narwhals clearly responded to the presence of Killer Whales (Figure 4). During the attack, both the north-

FIGURE 3. During the Killer Whale attack, Narwhals beached themselves in sandy areas and made tail slaps. Coastline can be seen in lower left. Photo by K. L. Laidre.

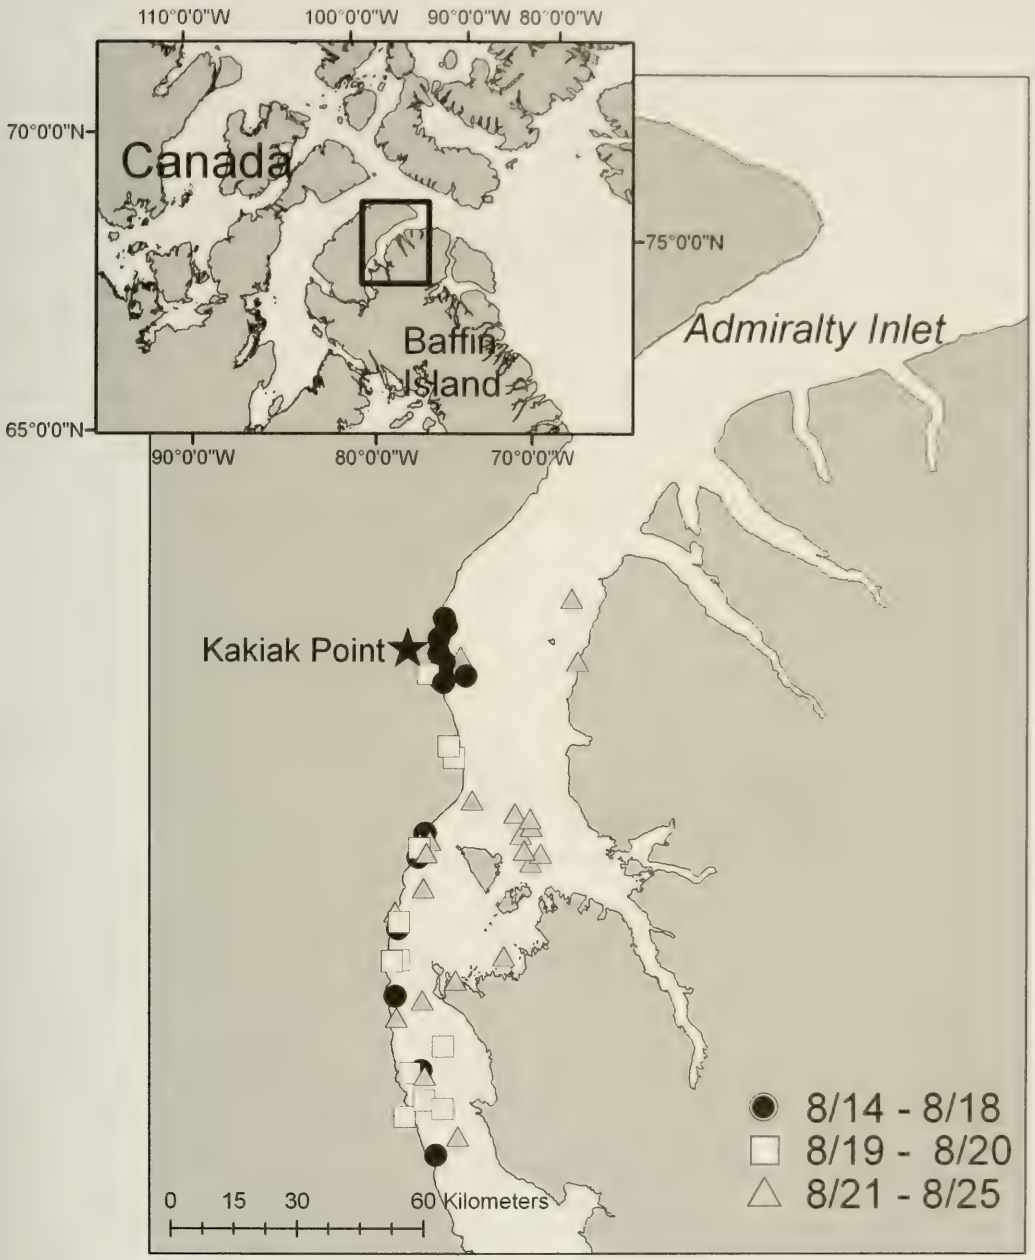

FIGURE 4. Average daily positions received from seven Narwhals instrumented with satellite tags before the Killer Whale attack. Average positions are shown in 3 time periods: the five days prior to Killer Whale arrival (14-18 August), the two days Killer Whales were observed (19-20 August), and the five days after the Killer Whale departure (21-25

south and west-east dispersal (as measured by inter-whale mean latitude and longitude standard deviations) doubled (Table 2). When Killer Whales were in the area, the core kernel home range shifted south by approximately 80 km and doubled in size (767 km^2) (Figure 5, Table 2). Generally, the groups of Narwhals were more widely dispersed in all directions during the attack than before the Killer Whales arrived.

Post-Attack Narwhal Behavior (>5 days)

Narwhals resumed their normal swimming behavior and distance from the coast within an hour after the Killer Whales left the locality. No whales were ob-

served closer than 20 m from the beach and tight groups at the surface broke-up and dispersed.

The instrumented Narwhals moved offshore and utilized a wider area after the attack (ANOVA on longitude, $F_{2,9}=17.6$, $P < 0.001$). Standard deviations of the mean inter-whale latitude (19.7 km) were reduced by half after the departure of the Killer Whales and were nearly identical to pre-attack values (19.9 km), demonstrating a contraction of the north-south dispersal (Table 2). The mean inter-whale longitude standard deviation was slightly lower than during the Killer Whale attack (27.6 km), yet did not return to pre-attack value, indicating a general inshore-offshore dispersal from the attack site.

Post-attack kernel home range core area (599 km^2) was less than that during the attack, yet the core area was located east of the pre-attack core in the center of Admiralty Inlet extending across to the eastern shoreline (Figure 5, Table 2). In general the Narwhal groups maintained a wider offshore dispersal and ranged more widely than before the Killer Whale attack.

Discussion

Narwhals exhibited clear reactions to the immediate presence of Killer Whales. Their suite of behaviors included slow, quiet movements, travel very close to the beach in the surf zone, movement into very shallow water less than 2 m, and formation of tight groups at the surface. All of these observations are consistent with Inuit accounts. Within an hour after the Killer Whale attack and when Killer Whales had left the area, direct observations suggested Narwhals resumed normal behavior (e.g., distances from the coast increased and tight groups dispersed).

Satellite telemetry data revealed long-term (multi-day) observations of Narwhal movements before and after the attack, in addition to observations during the attack. Average daily positions indicated that Narwhal groups were more dispersed during and after the Killer Whale attack. Dispersal primarily increased in the offshore (west-east) direction as measured by longitude standard deviations and home ranges. Cores of area use calculations demonstrated that the range of Narwhal movements increased two-fold during the Killer Whale attack, shifted south in a direction away from the attack point, and then expanded to offshore areas afterwards (where Narwhals had not been observed previously in 2005).

Later in the season, Killer Whales were reported in "fairly large numbers" in Admiralty Inlet and vicinity (especially Adams Sound) until October 2005 (Niore Annie Iqalukjuak, Arctic Bay, personal communication). The exact location and movements of these Killer Whales between August and September are not known, nor is it known whether other attacks on Narwhals occurred. Satellite tagging data showed that Narwhals remained in Admiralty Inlet until the third week of October, after which the southbound fall migration was underway. Thus, it appears that even on longer time scales (~2 months) Narwhals do not alter their site fidelity to the summering grounds (see Heide-Jørgensen et al. 2003) or depart early in response to the presence of Killer Whales.

Killer Whales were also reported in Admiralty Inlet in late August 2004 but no data or specific observations were available. It is unknown if the occurrence observed in 2004 involved the same group of Killer Whales as observed in 2005. On 25 August 2004, one of the authors (J.R.O.) observed a young Bowhead Whale (*Balaena mysticetus*) killed by Killer Whales at Kakiak Point, and bones were found on the beach less than 1 km away from the attack site the following year in 2005. Furthermore, on the same date as the attack reported here, several Killer Whales were observed attacking Narwhals in Repulse Bay, Hudson Strait, Canada (Joani Kringayark, personal communication). Therefore, at least two separate groups of Killer Whales feed on Narwhals on their summering grounds in the eastern Canadian Arctic in August.

When Killer Whales attacked Narwhals, there was limited action at the surface with no struggle or splashing observed. Killer Whales consumed the Narwhals below the surface of the water, and made multiple dives in the center of oiled areas (presumed kills) for 15-20 minutes. An eyewitness account of a Killer Whale attack on Narwhals in Inglefield Bredning, West Greenland in August 2004 noted Killer Whales jumping on top of Narwhals and holding them under the surface until they drowned (Gretchen Freund, personal communication).

If the predation level observed at Kakiak Point (4 Narwhals over 6 hours) is representative of the daily predation level of a similar sized pod of Killer Whales in the High Arctic, then consumption of Narwhals during a two-month stay in Admiralty Inlet would amount to approximately 200-300 Narwhals. A photographic survey estimated 5,556 (CV=0.22) Narwhals in Admiralty Inlet in 1984 (Richard et al. 1994). If the photographic survey results are corrected for whales that were diving using a correction factor of 0.38 (0.06) developed by Heide-Jørgensen (2004), then the abundance would have been in the order of 14,621(0.23). A mortality of 200-300 Narwhals from Killer Whale predation would represent <3% of this abundance estimate. It is possible that predation constitutes a larger proportion of the annual natural mortality of Narwhals than previously expected; however, it is not known if this natural mortality is fully compensatory. In this case, a continued high level of Killer Whale predation in combination with a population reduction by subsistence harvest could reinforce a decline. Killer Whale predation has been responsible for the decline of sea otters in Alaska (Estes et al. 1998; Doroff et al. 2003) and has been hypothesized as the driver for a decline of other top predators in the North Pacific (Springer et al. 2003).

The reason Narwhals occupy deep and narrow fjords during summer is unknown and it has been hypothesized that their summer distribution may be related to

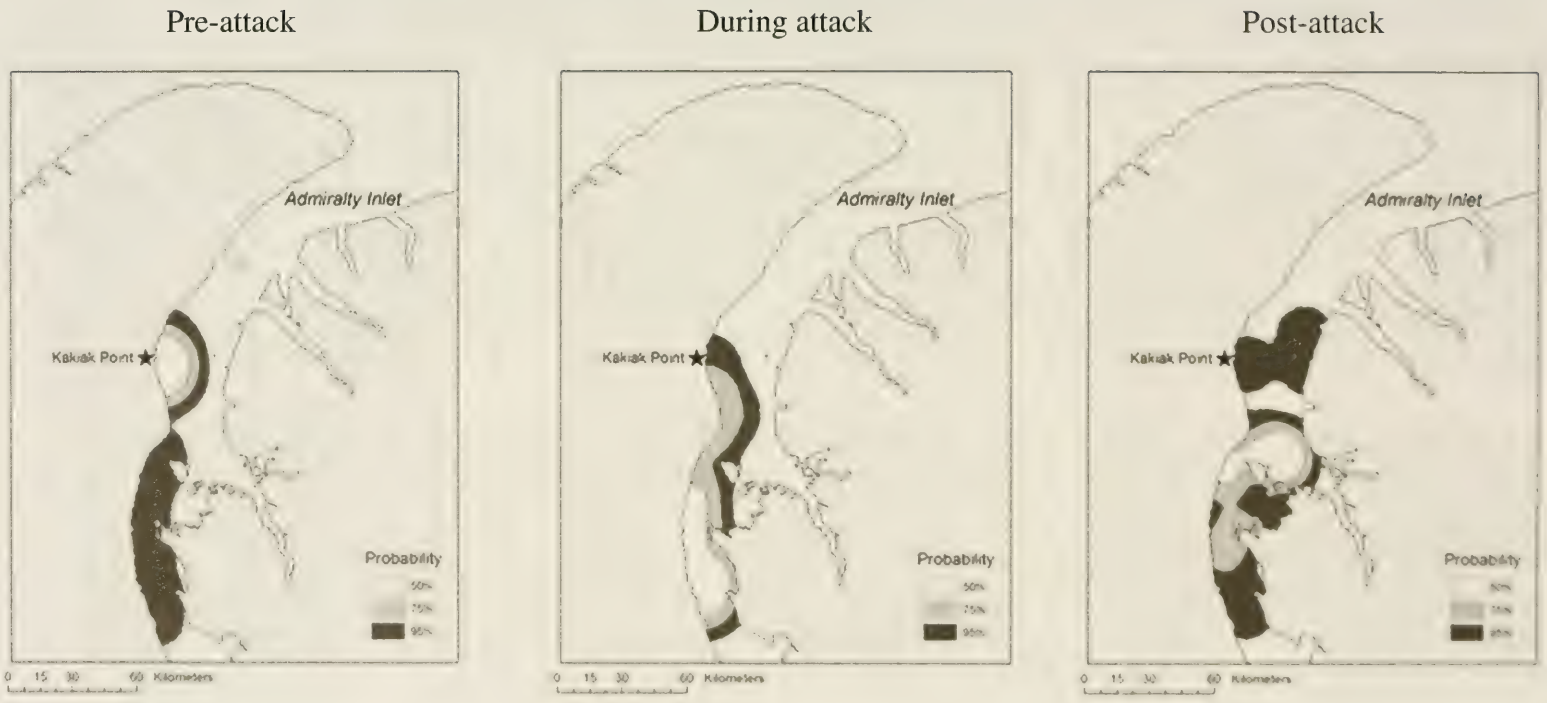

FIGURE 5. Narwhal space-use patterns before, during, and after the Killer Whale attack estimated with kernel home range polygons (50% is white). Home ranges were calculated for three time periods: The five days prior to Killer Whale arrival (14-18 August), the two days Killer Whales were observed (19-20 August), and the five days after the Killer Whale departure (21 August-25 August). The Killer Whale attack was observed at Kakiak Point (star symbol) on the west coast.

potential predation by Killer Whales (Kingsley et al. 1994). Narwhals feed very little during the summer season (Laidre and Heide-Jørgensen 2005a), and summering grounds do not appear to be related to calving needs given calves are born in the spring. The summer refuge from Killer Whales hypothesis lacks conclusive evidence as Narwhal distribution in other seasons is clearly driven by biological needs, such as sea ice formation, open water, or access to prey resources (Laidre and Heide-Jørgensen 2005b) and Narwhals did not seek refuge or depart early in response to the observed attack. Little is known about what proportion of different types of Killer Whales occurs in Arctic waters (i.e., mammal-eating vs. fish-eating). Stomach contents of 30 Killer Whales harvested in Disko Bay, West Greenland in February 2003 contained only Lumpsucker fish (*Cyclopterus lumpus*), despite the fact these Killer Whales were taken in an area with a large abundance of Bowhead Whales, Ringed Seals (*Phoca hispida*), Narwhals, Belugas, and other potential marine mammal prey items (Greenland Institute of Natural Resources, unpublished data).

Few observations have been collected of Killer Whales during winter in Arctic ice conditions. It is generally assumed that Killer Whales avoid the Arctic pack ice (Heide-Jørgensen 1988) despite the fact many Killer Whales occur and thrive in the dense pack-ice of the Antarctic. It is possible that changes in sea ice (lighter sea ice cover and earlier break-up) will alter (or have already altered) the occurrence of Killer Whales in Arctic waters. These changes may facilitate increased or longer visits by Killer Whales to ice-free Arctic areas.

The predicted reduction of annual sea ice, together with a longer open water season, will likely lead to an increase in Killer Whale predation on Narwhals. At the same time, reduced sea ice will also decrease the probability that Narwhals succumb in ice entrapments (also known as Sassats), another important source of natural mortality (Laidre and Heide-Jørgensen 2005b). It is unclear how the interplay between these two elements of natural mortality will evolve under changing sea ice regimes.

Acknowledgments

Research was funded by the Greenland Institute of Natural Resources, Fisheries and Oceans Canada, and the Nunavut Wildlife Management Board. The Polar Continental Shelf Project in Resolute supported logistics for field work in August 2005. The work was also supported by the Arctic Bay Hunters and Trappers Organization. Narwhal tagging was conducted under permits from Fisheries and Oceans Canada and Animal Care Permit FWISLACC#013. Robert Pitman, Randall Reeves, and an anonymous reviewer improved earlier drafts.

Mech, L. David 2006. Urine-marking and ground-scratching by free-ranging Arctic Wolves, *Canis lupus arctos*, in summer. Canadian Field Naturalist 120(4): 466–470.

Urine-marking and ground-scratching were observed in an Arctic Wolf (*Canis lupus*) pack on Ellesmere Island, Nunavut, Canada, during 16 summers between 1986 and 2005. All previously known urination postures and ground-scratching by breeding males and females were seen, and incidence of marking and scratching was greatest when non-pack wolves were present. Observations of urine-marking of food remains supported the conclusion from a captive Wolf study that such marking signals lack of edible food.

Key Words: Arctic Wolf, *Canis lupus arctos*, ground-scratching, odor, scent-marking, territoriality, urine-marking, Ellesmere Island, Nunavut, Canada.

Scent-marking by Wolves (*Canis lupus*) includes both urine-marking and ground-scratching, usually by dominant breeding males and females (Peters and Mech 1975; Harrington and Asa 2003). Most information about Wolf urine-marking has been collected during winter by tracking Wolves in the snow (Peters and Mech 1975; Rothman and Mech 1979; Paquet and Fuller 1990; Paquet 1991; Zub et al. 2003) or during other seasons by studying captive Wolves (Harrington 1981; Raymer et al. 1984, 1986; Asa et al. 1986, 1990; Mertl-Millhollen et al. 1986; Ryon and Brown 1990; Barja and Miguel 2004). Only scattered mentions can be found of free-ranging Wolves urine-marking during summer (Clark 1971; Haber 1977; Mech 1991, 1995), and only one study of Wolf ground-scratching in summer has been done (Zub et al. 2003). Detailed information about urine-marking in wild Wolves during summer is lacking because, with a few exceptions (Murie 1944; Clarke 1971; Haber 1977; Mech 1988), it has been difficult to observe Wolves in the wild during summer because of their usual fear and avoidance of humans.

I observed free-ranging Wolves in the Canadian High Arctic over a period of 20 summers, where the Wolves are highly tolerant of humans (Parmelee 1964; Miller 1978; Mech 1988). There I obtained detailed data on their urine-marking and ground-scratching behavior.

Study Area

The study area includes about 2600 km^2 of the Fosheim Peninsula east, north and west of Eureka on Ellesmere Island (80°N latitude, 86°W longitude), Nunavut, Canada. During summer, daylight is constant. The area includes shoreline, hills, lowlands, creek bottoms and the area around Blacktop Ridge. Contrary to much of the surrounding region, this area is generally snow- and ice-free in summer, and contains rock, gravel, bare soil and scattered tundra and northern wetland vegetation. Wolves, Muskoxen (*Ovibos moschatus*) and Arctic Hares (*Lepus arcticus*) have long been common in the area (Tener 1954), and Wolves have denned there over decades or possibly centuries (Parmelee 1964; Grace 1976; Mech 1988; Mech and Packard 1990). Aside from intermittent scavenging around a weather station and military base, the main foods of the Wolves I studied were Muskoxen and Arctic Hares (Tener 1954), although seals (*Phoca* spp.) and Lemmings (*Dicrostonyx groenlandicus*) are also taken occasionally.

Methods

The Wolves I studied live far enough from exploitation and persecution by humans that they are relatively unafraid of people (Mech 1988, 1995). During 1986, I habituated a Wolf pack to my presence and reinforced the habituation each summer I observed them. The pack frequented the same area each summer and usually used the same den or nearby dens. The habituation allowed me and an associate to remain with the Wolves daily, to recognize them individually, and to watch them regularly from 10 to 200-m away, and often as close as 1 m (Mech 1988, 1995). This pack had disappeared by 2001, but by 2003 another pack, similarly habituated, was present (Mech 2005).

Although I made no attempt to systematically or completely record every urination or scratching made by each Wolf, I did note as many such events as I could, usually those made by breeding males and females, while I was observing general behavior. I identified breeding females by observing them nursing pups or by the presence of obvious teats. Breeding males were identified by their dominance over other males and their

TABLE 1. Yearly distribution of observed urine marks made by breeding male (RLUs and STUs) and breeding female (FLUs and SQUs) Arctic Wolves, Ellesmere Island, Nunavut, Canada, 1986-1996, including only years in which observations covered at least four weekly periods.[1]
